COMISSÃO EXAMINADORA

Prof.^a Anete Pereira de Souza

Prof. Renato Vicentini dos Santos

Prof. Rafael Vasconcelos Ribeiro

Dr.^a Lilian Padilha

Dr.^a Letícia Aparecida de Castro Lara

Os membros da Comissão Examinadora acima assinaram a Ata de Defesa, que se encontra no processo de vida acadêmica do aluno.

A Ata da defesa com as respectivas assinaturas dos membros encontra-se no SIGA/Sistema de Fluxo de Dissertação/Tese e na Secretaria do Programa de Pós-Graduação em Genética e Biologia Molecular do Instituto de Biologia.

AGRADECIMENTOS

Agradeço primeiramente a orientadora professora Anete por ter me dado a oportunidade de ser seu aluno de iniciação científica e posteriormente confiado a mim o desenvolvimento de um projeto de pesquisa de doutorado direto em seu laboratório. Agradeço pelo apoio, pelo otimismo, pelo exemplo, pela preocupação e pela compreensão que fizeram com que esse longo período de pós-graduação fosse mais agradável e proveitoso.

Agradeço a Dra. Rosângela, minha coorientadora, que me auxiliou no entendimento e execução do projeto. Agradeço aos funcionários e técnicos do LAGM que sempre garantiram uma boa estrutura para a realização da pesquisa. Agradeço a todos os colegas de laboratório, que sempre foram muito solícitos a dividir seus conhecimentos e tornaram o ambiente de trabalho mais prazeroso. Agradeço a Aline, Alexandre e Rebecca que participaram ativamente do desenvolvimento desta tese, trabalhando juntos em diversos momentos. Especialmente a Aline que sempre esteve muito atenta a minha vida acadêmica me auxiliando em diversos aspectos e ao Alexandre que com seu conhecimento, empenho e dedicação me inspirou e auxiliou a desenvolver um trabalho que jamais faria sozinho. Agradeço ao professor Augusto da ESALQ, que se tornou uma grande inspiração para mim tanto como professor quanto como pesquisador, me mostrando a importância da estatística para a ciência.

Agradeço a minha família pelo auxílio financeiro que tornou possível a realização desta pós-graduação sem grandes preocupações. Agradeço aos meus amigos, tanto os que fiz antes da graduação e estão presentes em minha vida até hoje, quanto os que conheci na universidade e compartilharam a vida acadêmica comigo. Ter o apoio e companhia deles para roles, bares, festas e viagens foi essencial para a preservação da minha saúde mental.

Por fim, por acreditar em um mundo onde o conhecimento é democratizado, agradeço a todos que produzem e disponibilizam de forma gratuita materiais didáticos na internet, e que participam de fóruns de discussão compartilhando seus conhecimentos.

O presente trabalho foi realizado com apoio da Coordenação de Aperfeiçoamento de Pessoal de Nível Superior - Brasil (CAPES) - Código de Financiamento 001, da Fundação de Amparo à Pesquisa do Estado de São Paulo (FAPESP) e do Conselho Nacional de Desenvolvimento Científico e Tecnológico (CNPq).

RESUMO

Gramíneas forrageiras tropicais, especialmente espécies do gênero *Urochloa*, desempenham um importante papel na pecuária, sendo a principal fonte de alimento para os animais nas regiões tropicais e subtropicais. Apesar do melhoramento convencional de forrageiras ter liberado cultivares superiores nas décadas recentes, os ganhos genéticos foram baixos e o melhoramento molecular ainda não é usado devido aos escassos recursos genômicos e a alta complexidade genômica das espécies. Nesse cenário, essa tese tem como objetivo investigar métodos e técnicas de melhoramento molecular em forrageiras tropicais poliploides para produzir conhecimentos que auxiliem suas aplicações nos programas de melhoramento. Hibridização artificial e cruzamentos controlados em forrageiras são desafiantes devido a apomixia e a autogamia em certas espécies, e devido a outras situações que podem causar a inserção de contaminantes na população de interesse. Dessa forma, esta tese propõe uma metodologia multivariada semi-automatizada para a detecção e classificação de contaminantes em progênies poliploides biparentais, incluindo clones apomíticos, indivíduos de autofecundação, meios irmãos e contaminantes completos. A metodologia foi estabelecida utilizando dados de genotipagem por sequenciamento (GBS) processados para obtenção de marcadores SNP com informação de dosagem alélica, integrando análises de componentes principais (PCA), métricas genotípicas baseadas em segregação mendeliana e análises de clusterização. O método implementado no aplicativo polyCID permitiu, de forma rápida e simplificada, a identificação de todos os contaminantes em todas as progênies simuladas, e a detecção de contaminantes putativos em três progênies reais. Além disso, como a maioria das espécies forrageiras tropicais são apomíticas e tetraploides, *U. ruziziensis* tem uma importância ímpar por ser uma espécie diploide e sexual que pode ser tetraploidizada para ser usada em cruzamentos interespecíficos com espécies apomíticas. Assim, investigamos também a aplicabilidade de predição genômica de famílias (GWFP) em famílias de meios irmãos tetraploides de *U. ruziziensis* para prever crescimento e produção de biomassa. Aprendizado de máquina e seleção de features foram utilizados para reduzir a média 11 o número de marcadores necessários para a predição, e elevar a habilidade preditiva a aproximadamente 0.9 em todos os fenótipos. Ademais, para investigar a regulação das características agrônômicas, a posição dos marcadores de maior importância para a predição foram considerados como QTL putativos, e em uma abordagem multi-ômica, genes obtidos no transcriptoma da espécie fisicamente ligados aos marcadores foram mapeados. Uma rede de co-expressão foi modelada permitindo não apenas a investigação dos genes mapeados, mas também seus módulos de co-expressão. A anotação funcional mostrou que os

genes estão majoritariamente associados ao transporte de auxina e biossíntese de lignina, flavonols e ácido fólico, enquanto os genes co-expressos estão associados ao metabolismo de DNA, respostas a estresses e ao ritmo circadiano. A metodologia estabelecida fornece uma abordagem viável de melhoramento assistido por marcadores em forrageiras tropicais poliploides, e identificou regiões específicas para estudos moleculares futuros das características agronômicas investigadas. Esta tese mostra que os métodos e ferramentas do melhoramento molecular, desenvolvidos e amplamente aplicados em plantas modelo, podem ser adaptados para o melhoramento de espécies com genomas de alta complexidade, tais como as forrageiras tropicais, contribuindo para a formação de um arcabouço de conhecimento que auxiliará sua implementação nos programas de melhoramento dessas espécies.

Palavras-chave: forrageiras tropicais poliploides, melhoramento molecular, contaminantes, predição genômica, aprendizado de máquina, redes de co-expressão.

ABSTRACT

Tropical forage grasses, especially species of the genus *Urochloa*, play an important role in cattle production being the main food source for the animals in the tropical/subtropical regions. Although conventional breeding of tropical forage grasses has resulted in the release of superior cultivars in recent decades, the genetic gains are low and molecular breeding still not being used due to the genus' scarce genomic resources and genomic complexity. In this scenario, this thesis aims to investigate the application of molecular breeding methods and techniques in polyploid tropical forage grasses and produce useful knowledge to auxiliate breeding programs. Artificial hybridization and controlled crosses in tropical forages may be challenging especially due to apomixis and autogamy in certain species, and other situations that can cause the insertion of contaminants in the population of interest. This way, we proposed a semi-automated multivariate methodology for the detection and classification of putative contaminants, including apomictic clones, self-fertilized individuals, half-siblings, and full contaminants, in biparental polyploid progenies. We established a pipeline using genotyping-by-sequencing (GBS) data encoded as allele dosages of SNP markers by integrating principal component analysis, genotypic analysis measures based on Mendelian segregation, and clustering analysis. The method implemented in the fast and user-friendly polyCID app allowed the correct identification of all contaminants in all simulated progenies and the detection of putative contaminants in three real progenies. Furthermore, as most of the species are apomictic and tetraploid, *U. ruziziensis*, a sexual diploid species that can be tetraploidized to be used in interspecific crosses with apomictic species takes special importance. This way, we investigated the applicability of genome wide family prediction (GWFP) in tetraploidized *U. ruziziensis* half-sibling families to predict growth and biomass production. Machine learning and feature selection algorithms were used to reduce the number of markers necessary for prediction to approximately 11 markers and to enhance the predictive ability to approximately 0.9 across the phenotypes. Beyond that, to investigate the regulation of the agronomic traits, the position of the markers with more importance for the prediction were considered as putative QTLs, and in a multi-omic approach, genes obtained in the species transcriptome were mapped linked to those markers. Furthermore, a gene co-expression network was modeled enabling not only the investigation of the mapped genes but their co-expressed genes too. The functional annotation showed that the mapped genes are mainly associated with auxin transport and biosynthesis of lignin, flavonol and folic acid, while the co-expressed genes are associated with DNA metabolism, stress response and circadian rhythm. The methodology provided a viable marker-assisted breeding approach for

tropical forages and identified target regions for future molecular studies on these agronomic traits. This thesis shows that molecular breeding methods and tools, developed and broadly applied in model plants, with the necessary adjustments, can be used in the breeding of orphan species with high complexity genome like the tropical forages, contributing to the formation of a knowledge that will auxiliate its implementation in those species breeding programs.

Keywords: polyploid tropical forages, molecular breeding, contaminants, genomic prediction, machine learning, co-expression networks.

ORGANIZAÇÃO DA TESE

Esta tese está organizada em oito partes que se iniciam a partir de uma **Introdução Geral**, onde são abordados os principais aspectos do cultivo de forrageiras tropicais no Brasil, indicando a sua importância e as dificuldades encontradas pelos programas de melhoramento. Em seguida, é apresentada uma breve **Revisão Bibliográfica** acerca dos principais assuntos abordados nos capítulos, e então são apresentados os **Objetivos Gerais e Específicos** que foram investigados e alcançados nos capítulos.

No **Capítulo I** desenvolvemos uma ferramenta para a identificação semi automática de contaminantes em populações biparentais tetraplóides e hexaplóides utilizando marcadores SNPs. Implementada em um R Shiny web app chamado polyCID, com interface visual para facilitar seu uso, nossa metodologia integra análises de componentes principais (PCA), análises de genótipo e algoritmos de agrupamento para identificar contaminantes. Em nossas simulações, obtivemos 100% de identificação correta em populações compostas por 200 indivíduos genotipados com mais de 689 marcadores. A metodologia foi aplicada em três populações reais de forrageiras tropicais, duas tetraploides (*U. decumbens* e *M. maximus*) e uma hexaploide (*U. humidicola*), e foram identificados contaminantes do tipo clone apomíticos em todas as populações.

No **Capítulo II** investigamos a aplicabilidade de predição genômica em bulks de famílias de meios irmãos em *U. ruziziensis*, e os processos metabólicos envolvidos na expressão das características preditas. A população foi genotipada por GBS (do inglês Genotyping-By-Sequencing) e fenotipada em nove cortes para características agronômicas relacionadas a produção de biomassa e crescimento. Modelos convencionais e de aprendizado de máquina foram comparados, assim como subconjuntos de marcadores obtidos através de métodos de seleção de *features*. Obtivemos uma média de aproximadamente 0.9 de habilidade preditiva utilizando conjuntos de em média 11 marcadores por característica. Com um transcriptoma da espécie, construímos uma rede de co-expressão, e identificamos os genes que estão fisicamente ligados aos marcadores de maior importância para a predição. A partir da anotação funcional destes genes e daqueles co-expressos, obtivemos um panorama restrito e um amplo dos processos biológicos que atuam na regulação das características agronômicas investigadas.

Após os capítulos, um breve **Resumo dos Resultados** está descrito, seguido pelas **Conclusões Gerais** relacionadas aos capítulos e por fim as **Perspectivas** referentes a pesquisa desenvolvida na tese.

INTRODUÇÃO

As gramíneas forrageiras tropicais são de extrema importância para a pecuária brasileira, compondo a base da alimentação bovina do país e influenciando no custo da produção da carne e do leite, e na segurança alimentar (Dias-Filho, 2016). As pastagens formadas por essas gramíneas forrageiras ocuparam cerca de 163 milhões de hectares e permitiram alimentar um rebanho total de 196 milhões de cabeças no ano de 2021 (ABIEC, 2022). Esses valores posicionaram o Brasil como portador do maior rebanho bovino e principal exportador do planeta, fazendo com que a pecuária total representasse aproximadamente 10% do PIB nacional (ABIEC, 2022). Paralelamente ao mercado da carne, o comércio brasileiro de sementes de forrageiras tropicais também possui grande importância econômica. Devido ao desenvolvimento de pastagens melhoradas, o Brasil passou a ser o maior produtor, consumidor e exportador dessas sementes, movimentando cerca de 440 milhões de dólares por ano, o que representa 11% do mercado de sementes no Brasil (Jank et al., 2014; Campante, 2019).

Estima-se que mais da metade das pastagens cultivadas no Brasil sejam formadas por gramíneas do gênero *Urochloa* (Macedo, 2006), e as espécies de maior importância neste gênero são: *U. brizantha*, *U. decumbens*, *U. ruziziensis* e *U. humidicola*, todas de origem africana e com níveis de ploidia variados (Renvoize et al, 1996). A introdução comercial de espécies do gênero *Urochloa* nas pastagens brasileiras é relativamente recente, sendo a primeira em 1952 com um acesso de *U. decumbens* (cv. Ipean) (Valle et al., 2008). Ao longo do tempo, devido a problemas especialmente relacionados a cigarrinhas-das-pastagens, fotossensibilização e baixa produtividade, a pecuária brasileira sofreu grandes prejuízos, o que incentivou a busca por novas cultivares. A fim de mitigar problemas como esses através do melhoramento de espécies e diversificação das pastagens, a Empresa Brasileira de Pesquisa Agropecuária (Embrapa) trouxe para o Brasil parte do germoplasma coletado entre 1984 e 1985 no leste africano pelo Centro Internacional de Agricultura Tropical (CIAT) (Valle, 1990; Valle et al., 2008).

Uma importante característica das forrageiras tropicais é a capacidade de se reproduzir por apomixia, que é uma forma assexual de reprodução na qual são geradas sementes geneticamente idênticas à planta mãe, fazendo com que a progênie seja composta por clones (Bicknell, 2004). Apesar de ser muito interessante devido a possibilidade da fácil fixação de genótipos superiores, os programas de melhoramento acabam tendo dificuldades para realizar cruzamentos devido a ausência de genótipos sexuais. Nesse contexto, o que tem sido feito é a poliploidização de genótipos diplóides sexuais para que sejam utilizados em

cruzamentos com genótipos poliploides apomíticos (Simioni e Valle, 2009, Euclides et al., 2010; Jank et al., 2014). Ainda que haja formas de identificar se a planta é apomítica ou não, como por exemplo através da análise de sacos embrionários (Valle, 1990), há a possibilidade da planta diplóide sexual ao ser poliploidizada se tornar apomítica facultativa e expressar essa característica apenas em situação de campo, contaminando progênes híbridas com clones apomíticos.

A *Urochloa ruzizensis* é a principal espécie utilizada para poliploidização e aplicação como genitor feminino em cruzamentos interespecíficos no gênero *Urochloa*. Além disso, é uma espécie com alta qualidade nutricional (Simioni e Valle, 2009; Timbó et al., 2014) e de importância para a sustentabilidade do agronegócio brasileiro, sendo muito utilizada em sistemas integrados que unem lavoura, pecuária e floresta (Balbino et al., 2011). Apesar de sua importância, e tendo sido utilizada para o lançamento de diversas cultivares híbridas, o melhoramento específico de *U. ruzizensis* ainda é muito recente e teve sua primeira cultivar lançada pela Embrapa em 2022, a BRS Integra.

Nesse contexto, técnicas e métodos de melhoramento molecular, como a genotipagem, construção de mapas genéticos, mapeamento de QTL, seleção/predição genômica e análises de transcriptoma ainda são pouquíssimos utilizados e investigados na espécie. Dessa forma, este trabalho teve dois objetivos principais para expandir o conhecimento relacionado ao melhoramento molecular de gramíneas forrageiras tropicais: (1) desenvolvimento de uma ferramenta capaz de fazer a identificação de contaminantes em populações biparentais tetra e hexaploides genotipadas com marcadores SNPs; (2) avaliar a aplicação de GWFP (predição genômica ampla em famílias) em *U. ruzizensis* e através de uma abordagem multi ômica investigar vias metabólicas que atuam na regulação dos fenótipos avaliados.

REVISÃO BIBLIOGRÁFICA

Gênero *Urochloa*: importância e melhoramento genético

O gênero *Urochloa* P. Beauv. (sinonímia *Brachiaria* (Trin.) Griseb.) é pertencente à família Poaceae, à subfamília Panicoideae e à tribo Paniceae, e possui diversas espécies distribuídas em regiões tropicais e subtropicais, em habitats que vão desde várzeas inundáveis até savanas (Valle et al., 2009). No Brasil, estima-se que mais de 50% da área de pastagem plantada são cultivadas com espécies do gênero *Urochloa* (Figueiredo et al. 2012), sendo que as mais utilizadas são *U. brizantha*, *U. decumbens*, *U. ruziziensis* e *U. humidicola*, todas de origem africana e com níveis de ploidia variados (Renvoize et al, 1996). A importância do gênero para o desenvolvimento da pecuária no Brasil reside no fato de que a alimentação de ruminantes é realizada em pastos, de onde estes animais retiram aproximadamente 90% dos nutrientes que consomem (Euclides et al. 2010). Por possuírem características essenciais como a alta produção de matéria seca, elevada adaptação a diversos tipos de solos e variabilidade para resistência a pragas e doenças, algumas espécies do gênero são ótimas opções para serem usadas como pastagens (Valle et al., 2008; Figueiredo, 2011; Mendonça, 2012).

A introdução comercial de espécies do gênero *Urochloa* nas pastagens brasileiras é relativamente recente, sendo a primeira em 1952 com um acesso de *U. decumbens* (cv. Ipean), que apresentou baixa produção de sementes. Na década seguinte, outra cultivar de *U. decumbens* foi introduzida, conhecida como cv. Basilisk, a qual apresentou excelente adaptação às condições locais e rapidamente tornou-se a principal espécie de forrageira do país. No mesmo período, houve a introdução de cultivares de *U. ruziziensis*, *U. humidicola* e *U. arrecta* (Valle et al., 2008). No início da década de 1980, a monocultura de *U. decumbens* passou a apresentar sérios problemas, tais como a suscetibilidade à cigarrinha-das-pastagens e a fotossensibilização de animais, acarretando em grandes prejuízos para a pecuária brasileira. A busca por novas cultivares para solucionar esses problemas levou ao lançamento da primeira cultivar de *U. brizantha* em 1984, chamada de cv Marandu, a qual passou a substituir gradualmente as pastagens de *U. decumbens* por possuir diversos atributos agrônômicos relevantes, dentre eles, a resistência às cigarrinhas-das-pastagens (Nunes et al., 1984).

Nesse contexto, devido à necessidade de diversificação das pastagens e aumento da produtividade, foi imprescindível a obtenção de um banco de germoplasma de *Urochloa* para dar início aos programas de melhoramento. Sendo assim, viagens de coleta foram realizadas durante 1984 e 1985 no leste africano, região com grande diversidade e dispersão do gênero

(Valle et al., 2008) pelo Centro Internacional de Agricultura Tropical (CIAT) (Keller-Grein et al., 1996; Miles e Valle, 1996), e boa parte do material coletado foi duplicado e trazido para o Brasil para constituir a coleção da Empresa Brasileira de Pesquisa Agropecuária (Embrapa), que é utilizada até hoje pelos programas de melhoramento. Além dos germoplasmas já citados pertencentes ao CIAT e a Embrapa, são mantidos mais cinco germoplasmas de *Urochloa* distribuídos pelo mundo. Sendo os do Centro Internacional de Pecuária da África - ILCA, do Centro de Recursos Genéticos de Forrageiras Tropicais Australiano - ATFGRC/CSIRO, do Departamento de Agricultura dos Estados Unidos - USDA, do Germoplasma Nacional do Quênia - GBK e do Instituto Pasteur Roodeplaat/Conselho Africano de Pesquisa - RGI/ARC (Keller-Grein et al., 1996).

Apesar da obtenção do germoplasma, os programas de melhoramento ainda tinham um grande desafio a ser superado. As principais espécies do gênero (*U. brizantha*, *U. decumbens* e *U. humidicola*) são predominantemente apomíticas, isso é, se reproduzem assexuadamente através de sementes (Valle et al., 2008, Valle et al., 2009). Essa característica limita o melhoramento das espécies, já que na ausência de parentais sexuais, não é possível realizar cruzamentos, deixando a princípio apenas a seleção direta no germoplasma como forma de lançar cultivares (Jank et al., 2005; Miles, 2007). Ainda que a seleção direta seja uma forma rápida e simples de melhoramento, raramente uma planta apomítica possui todos os caracteres de interesse. Para superar esse obstáculo, a espécie *U. ruziziensis*, originalmente diploide e sexual, teve sete genótipos poliploidizados artificialmente (Swenne et al. 1981). Dessa forma, em conjunto com as espécies tetraploides *U. brizantha* e *U. decumbens*, esses novos genótipos formaram um complexo agâmico, possibilitando a realização de cruzamentos inter-específicos e a obtenção/seleção de híbridos superiores (Valle et al., 2008, Valle et al., 2009). Embora a apomixia represente uma limitação para a realização de cruzamentos, é uma característica de muita importância para a comercialização de cultivares de gramíneas forrageiras. Genótipos superiores que se reproduzem por apomixia podem ter seus clones comercializados através de suas sementes, sendo fácil a obtenção de grandes quantidades de sementes e garantindo uma maior uniformidade no cultivo.

O estudo e a avaliação dos germoplasmas pelos programas de melhoramento permitiu que diversos cultivares fossem lançados. Atualmente existem 20 cultivares comercialmente disponíveis no mundo, cultivares das espécies *U. ruziziensis* (Kennedy e BRS Integra), *U. brizantha* (Marandu, MG-4, Xaraés, BRS Piatã, BRS Paiaguás, Braúna MG 13 e BRS Ybaté), *U. decumbens* (Basilisk) e *U. humidicola* (BRS Tupi), além de diversas cultivares híbridas de *U. ruziziensis* com as espécies tetraploides, sendo a Embrapa e a Barenbrug do

Brasil Sementes LTDA as instituições responsáveis por boa parte dos cultivares (Ferreira et al., 2021).

Comparado a outras gramíneas de importância, como trigo e arroz, o conhecimento genético/genômico do gênero *Urochloa* é muito restrito, fazendo com que a aplicação de métodos de melhoramento molecular, como por exemplo através seleção assistida por marcadores, seja muito limitado. Apesar de características intrínsecas como o modo de reprodução e a poliploidia, e também baixos investimentos dificultarem os estudos no gênero, os avanços das tecnologias genômicas e a redução de seus custos, aliados ao surgimento de métodos estatísticos apropriados, permitiram considerável progresso no conhecimento genético/genômico dessas espécies nos últimos anos.

Dentre esses avanços está principalmente o desenvolvimento de marcadores moleculares, que a princípio foram utilizados para estudos de diversidade genética. Com marcadores do tipo microsatélite (SSR) foram feitos trabalhos em painéis de genótipos com mais de uma espécie do gênero (Chiari et al., 2008; Almeida et al., 2011; Garcia et al., 2013; Kuwi et al., 2018; Namazzi et al., 2020), em acessos de *U. humidicola* (Jungman et al., 2009a; Jungmann et al., 2010; Santos et al., 2015; Vigna et al., 2016a), *U. brizantha* (Jungmann et al., 2009b; Vigna et al., 2011; Braga et al., 2017; Tegegn et al., 2019), *U. decumbens* (Ferreira et al., 2016; Souza et al., 2018) e *U. ruziziensis* (Azevedo et al., 2011; Silva et al., 2013; Pessoa-Filho et al., 2015). Além da avaliação de diversidade, marcadores moleculares também foram utilizados para construir mapas genéticos. Até o momento existem mapas para populações híbridas (Worthington et al., 2016; Thaikua et al., 2016; Worthington et al., 2021), para *U. humidicola* (Vigna et al., 2016a, Worthington et al., 2019) e para *U. decumbens* (Ferreira et al., 2016), que foram construídos com marcadores SSR e SNP. Já em relação a associação genômica ampla (GWAS) e seleção genômica, os estudos são ainda mais escassos. Ambas metodologias foram investigadas em uma população híbrida do cruzamento entre *U. brizantha* e *U. ruziziensis* (Matias et al., 2019a; Matias et al., 2019b) e seleção genômica foi avaliada em uma população biparental de *U. decumbens* (Aono et al., 2022), os três trabalhos foram realizados utilizando marcadores SNPs.

Além de trabalhos com genotipagem, também estão disponíveis estudos de transcriptoma com espécies do gênero. A primeira investigação a nível de transcritos foi realizada utilizando material foliar de dois genótipos contrastantes de *U. humidicola* coletados em condições de campo (Vigna et al., 2016b). Com o objetivo de investigar as bases moleculares da resistência a estresses abióticos, foram realizadas análises de transcriptoma em *U. decumbens* (Basilisk) por Salgado et al. (2017) e por Worthington et al.

(2021), que também utilizou no estudo o genótipo de *U. ruziziensis* (BRX 44-02). Já o trabalho de Jones et al. (2021) foi feito utilizando híbridos interespecíficos para estudar as respostas ao estresse causado pela falta de água. Por fim, o trabalho mais recente envolvendo RNA-seq, foi feito com um painel diverso de espécies do gênero *Urochloa* com o objetivo de identificar alelos LOF (*loss-of-function*) relacionados a digestibilidade e conteúdo lipídico da biomassa produzida pelas plantas (Hanley et al., 2021).

Espécie *U. ruziziensis*: importância e melhoramento genético

A espécie *Urochloa ruziziensis* (R. Germ. and C.M. Evrard), também conhecida como: “Congo signal grass”, “Congo grass” e “Ruzi grass”, é originária da África, sendo encontrada principalmente no vale do rio Ruzizi, que fica na divisa entre a República Democrática do Congo, Burundi e Ruanda, em áreas de solos frescos e não inundáveis (Keller-Grein et al. 1996). Quanto às suas características morfológicas, *U. ruziziensis* é uma espécie perene com 1-1.5 m de altura, rizomas curtos, robustos e globosos; nós comprimidos, de cor escura e glabros; lâmina linear-lanceolada, de 10 a 30 cm de comprimento, 10 a 15mm de largura, pubescentes, verde amarelada, esparsamente pilosa; possui rizomas fortes, em forma de tubérculos arredondados e com até 15 mm de diâmetro; inflorescência em panícula com racemos bilaterais, terminais, de 15 a 25 cm de comprimento com 3 a 7 às vezes até 9 ramificações primárias e alternas; a inflorescência está formada por 3-6 racemos de 4-10 mm de comprimento; ráquis largamente alada, com 4 mm de largura, geralmente de cor arroxeadas; espiguetas de 8 a 5 mm de comprimento, pilosas na parte apical, bisseriadas ao longo da ráquis; a gluma inferior tem 3 mm de comprimento e surge de 0.5 a 1 mm abaixo do resto da espiguetas e o flósculo fértil apresenta 4 mm de comprimento (Seiffert, 1980; Valle et al., 2010).

Em relação a suas características agronômicas, a espécie possui um estabelecimento e crescimento rápido, que ocorre geralmente no início do período das chuvas, e seu florescimento é concentrado com alta produção de sementes (Valle et al. 2010). A biomassa produzida por essa pastagem possui elevado valor nutricional, com altas taxas de degradabilidade da matéria seca e da proteína bruta, baixo teor de fibra em detergente neutro e alta aceitação pelo gado, devido à boa palatabilidade (Simioni and Valle 2009; Lopes et al. 2010; Souza Sobrinho et al. 2010; Timbó et al. 2014). Apesar dessas boas características, a espécie apresenta baixa adaptação a solos mal drenados e de baixa fertilidade, alta suscetibilidade às cigarrinhas das pastagens, baixa competição com invasoras e baixa tolerância à seca (Valle et al. 2010). Uma interessante característica da espécie é sua

importância para a sustentabilidade do agronegócio brasileiro, sendo muito utilizada em sistemas integrados, tais como ILP e ILPF, que unem lavoura, pecuária e floresta (Balbino et al., 2011). Esse sistemas reúnem atributos raros em outros sistemas de produção de alimentos, são mais eficientes no uso dos recursos naturais (Wright et al., 2012), promovem ciclagem de nutrientes e melhoria do solo (Salton et al., 2014), reduzem os custos de produção mantendo níveis de produtividade elevados (Ryschawy et al., 2012; Balbinot et al., 2009) e produzem inúmeros serviços ecossistêmicos (Sanderson et al., 2013).

Pelo fato de ser possível obter artificialmente tetraplóides sexuais de *U. ruziziensis*, a representatividade da espécie dentre as cultivares de *Urochloa* disponíveis no mundo se dá principalmente em cultivares híbridas. Atualmente estão disponíveis apenas as cultivares Kennedy (1966) e BRS Integra (2020) especificamente de *U. ruziziensis*, enquanto cultivares híbridas estão disponíveis: Mulato I e II (2000, 2005), Mixe Drwn 12 e LN 45 (ambas de 2013), BRS RB331 Ipyporã (2017), Cayana (2020), Convert 330 (2021) e BARG156 780J (2021), que são resultado de hibridações com *U. brizantha* e *U. decumbens* (Ferreira et al., 2021).

Quanto a genética e aos recursos genético/genômicos da espécie, avaliações citogenéticas mostraram que as plantas diplóides apresentam 18 cromossomos ($2n = 2x = 18$) (Bernini and Marin-Morales, 2001) e as artificialmente poliploidizadas apresentam 36 cromossomos ($2n = 4x = 36$) (Timbó et al., 2014), e investigaram o comportamento dos cromossomos em todas as fases da meiose (Risso-Pascotto et al., 2003; Risso-Pascotto et al., 2005). Dentro do gênero, *U. ruziziensis* é a única espécie que possui o genoma sequenciado, dos dois sequenciamentos disponíveis ambos são de indivíduos diplóides, um deles está a nível de cromossomo, obtido do genótipo “C6” através do sequenciamento PacBio baseado na tecnologia SMRT (*Single Molecule Real Time*) (Pessoa-Filho et al., 2019), e o outro, do genótipo CIAT 26162, a nível de *scaffolds*, que foi obtido por WGA (*Whole Genome Assembly*) através da montagem de *reads* curtos (Worthington et al., 2021).

Além do genoma sequenciado, a espécie possui marcadores moleculares do tipo microsatélite (SSR) identificados, esses marcadores foram desenvolvidos principalmente para avaliações de diversidade, como nos trabalhos de Azevedo et al. (2011) e Pessoa-Filho et al. (2015), que reportaram alta diversidade e alta heterozigosidade nos painéis de genótipos. Além desses dois trabalhos, Silva et al. (2013) validou um conjunto de marcadores SSR identificados através de uma montagem do genoma parcial *de novo* utilizando *reads* Illumina *single-end*, que podem ser utilizados em análises genéticas e em seleção assistida por marcadores. Apesar de não especificamente com populações de *U. ruziziensis*, mapas

genéticos foram construídos para populações híbridas obtidas de cruzamentos com outras espécies do gênero. O primeiro foi construído utilizando marcadores AFLP para uma população oriunda do cruzamento entre a cultivar apomítica “Mulato” e a cultivar de *U. ruziziensis* “Miyaokikoku” (Thaikua et al., 2016). Depois, já com marcadores do tipo SNP, mais dois mapas foram construídos utilizando cruzamentos envolvendo os acessos sexuais tetraploidizados BRX 44-0 e BRX 44-2 com o acesso CIAT 606 da cultivar Basilisk de *U. decumbens* (Worthington et al. 2016; Worthington et al. 2021). Ademais, para investigar as bases moleculares da tolerância a solos com alumínio, foi feito um transcriptoma dos acessos BRX 44-2 e CIAT 606 comparando os perfis de expressão sob situação de alta concentração ou ausência de alumínio no solo (Worthington et al. 2021). Já o trabalho de Hanley et al. (2021) que investigou um painel diverso de *Urochloa*, é o mais recente que produziu dados de RNA-seq de plantas da espécie *U. ruziziensis*, estando incluso no painel 11 genótipos da espécie.

Identificação de contaminantes

Um dos problemas relacionados ao método de artificialmente poliploidizar genótipos sexuais de gramíneas forrageiras tropicais é a possibilidade da planta passar a ser apomítica facultativa, sendo capaz de produzir simultaneamente híbridos oriundos do cruzamento de interesse e clones apomíticos (Smith, 1972). Ainda que seja possível avaliar a apomixia nos genótipos através da análise de sacos embrionários (Valle, 1990), plantas que apresentam apomixia facultativa podem não expressar a característica durante a avaliação. Além disso, devido ao sistema reprodutivo dessas plantas e a anemofilia (polinização das flores por ação do vento), existe a possibilidade de indivíduos serem gerados por autofecundação ou por fecundação através de pólen vindo de outro campo (Bateman, 1947; Simeão et al., 2016). Somando as situações descritas a ocorrência de erros durante a coleta e manejo de sementes, mesmo em cruzamentos controlados, contaminantes como clones apomíticos, progênies de autofecundação e híbridos de cruzamentos inesperados podem ser inseridos nas populações de interesse. O comprometimento de progênies puramente híbridas, a depender do nível de contaminação, pode trazer grandes vieses para análises genéticas e genômicas, como testes de segregação e de desequilíbrio de ligação, construção de mapas genéticos e mapeamento de QTL, que são fundamentais para o entendimento das relações entre genótipo e fenótipo (Kemble et al., 2019).

Tradicionalmente, a identificação de híbridos tem sido feita através de caracteres morfológicos e marcadores microssatélite (SSR) (Santos et al., 2014; Jha et al., 2016; Zhao et

al., 2017; Patella et al., 2019), que são métodos com diversas desvantagens. Análises de características morfológicas demandam muito tempo, apresentam baixo rendimento e possuem acurácias que são influenciadas por fatores ambientais (Zhao et al., 2017). Já o desenvolvimento de marcadores microsatélites é um processo demorado e trabalhoso, que depende de informações genômicas obtidas previamente, desenvolvimento de *primers* específicos e otimização da técnica de PCR (*Polymerase Chain Reaction*) (Vieira et al., 2016), além de apresentar frequentemente erros de genotipagem em poliploides (Guichoux et al., 2011; Hodel et al., 2016). Nesse sentido, os marcadores SNPs, que podem ser obtidos através dos métodos de genotipagem baseados em sequenciamento de nova geração, como o GBS (*genotyping-by-sequencing*) (Elshire et al. 2011; Poland et al., 2012), podem ser obtidos rapidamente, por preços acessíveis e de forma confiável em espécies com pouca informação genômica disponível e com grandes genomas, como as espécies poliploides (Elshire et al., 2011; Poland et al., 2012; Ferreira et al., 2019; Deo et al., 2020; Mollinari et al., 2020).

Atualmente, existem alguns *software* capazes de atribuir paternidade ou nível de parentesco entre amostras diplóides, fazendo uso de marcadores microsatélites ou SNPs através de diferentes métodos estatísticos (Kalinowski et al., 2007; Jones and Wang, 2010; Hayes, 2011; Anderson, 2012; Heaton et al., 2014; Huisman, 2017; Grashei et al., 2018; Whalen et al., 2019). Para poliploides, os programas estão limitados a marcadores microsatélites (Spielmann et al., 2015; Zwart et al., 2016), ou métodos para estimar índices de parentesco porém incapazes de classificar amostras (Huang et al., 2015; Amadeu et al., 2020). Ainda que haja opções para tentar identificar contaminantes em populações biparentais poliploides, as ferramentas não foram desenvolvidas especificamente para essa tarefa, o que acaba demandando alto conhecimento da ferramenta e do método pelo usuário para que a análise seja adaptada a esse objetivo.

Predição e seleção genômica

Seleção genômica é um método de melhoramento assistido por marcadores moleculares proposto por Bernardo (1994) e amplamente difundido pelo trabalho de Meuwissen et al. (2001). O método se baseia no uso de dados de genotipagem e fenotipagem para desenvolver modelos de predição capazes de estimar valores genéticos de amostras que foram apenas genotipadas. Isso é possível porque com a obtenção de muitos marcadores que cobrem todo o genoma, parte desses marcadores estarão em desequilíbrio de ligação com os QTL que influenciam a característica (Meuwissen et al. 2001). As principais vantagens da seleção genômica estão relacionadas a redução dos gastos e do tempo necessário para o

processo de melhoramento. Além de não ser necessário fazer a fenotipagem, que é um processo caro, as plantas podem ser avaliadas logo que brotam, não sendo necessária a manutenção da população no campo por muito tempo (Simeão-Resende et al., 2014, Crossa et al., 2017).

As populações necessárias para a realização de um programa de seleção genômica geralmente são três, essas populações são conjuntos de genótipos nos quais os modelos preditivos são treinados, validados e aplicados. A primeira população é chamada de população de treino, os indivíduos dessa população são genotipados e fenotipados para as características de interesse e, a partir desses dados, o modelo estatístico é treinado, criando a relação entre os valores genéticos e os marcadores. A segunda população é chamada de população de teste, a qual geralmente é uma população menor que a de treino, mas também possui seus indivíduos genotipados e fenotipados. A função dessa população é avaliar a performance do modelo de predição genômica, comparando os valores estimados com os valores reais observados. Por fim, a terceira população é a de melhoramento, nessa população os indivíduos são apenas genotipados e seus valores genéticos são estimados pelo modelo previamente treinado, podendo haver assim a seleção das melhores amostras sem a necessidade da fenotipagem (Goddard e Hayes, 2007; Nakaya e Isobe, 2012; Desta e Ortiz, 2014).

Muitas vezes a população de treino e teste são a mesma população e a modelagem é avaliada através do método de validação cruzada, nesse método a população genotipada e fenotipada é dividida em " k " grupos, dos quais " $k-1$ " são utilizados como população treino e o último grupo como população de teste, isso é feito " k " vezes de forma que todos os grupos sejam utilizados tanto como treino quanto como teste. Em cada rodada da validação cruzada, as métricas de avaliação são computadas e por fim uma média é obtida. Das métricas utilizadas para avaliar modelos de regressão, as mais utilizadas em seleção genômica são a habilidade preditiva (coeficiente de correlação de Pearson) e o erro quadrático médio (Schulz-Streeck et al., 2012; Ould Estaghvirou et al., 2013).

Desde que a seleção genômica foi proposta, diferentes modelos estatísticos foram investigados. Dentre os mais aplicados, estão os modelos paramétricos lineares mistos, como o RR-BLUP, GBLUP e Bayes(A,B,C), modelos semi-paramétricos como o RKHS e modelos não paramétricos, como os algoritmos de aprendizado de máquina: SVM, RF e redes neurais (VanRaden, 2008; Endelman, 2011; Pérez et al., 2014; Wang et al., 2018; Montesinos-López et al., 2021). Quando comparados, geralmente o melhor modelo varia a depender da espécie e do fenótipo avaliado, não havendo assim um modelo que seja superior aos outros em todas as

situações. Além do modelo, a acurácia da seleção genômica é afetada por vários fatores, como o tamanho amostral, distância genética, densidade de marcadores, herdabilidade e desequilíbrio de ligação entre marcadores e QTL (Wang et al., 2018).

No caso de *U. ruziziensis* e outras espécies forrageiras, como alfafa e azevém, que podem ser melhoradas através de seleção de famílias completas ou de meios irmãos (Simeão et al., 2012; Simeão et al., 2016a,b; Biazzi et al., 2017; Cericola et al., 2018; Jia et al., 2018; Andrade et al., 2022), a aplicação de GWFP (predição genômica ampla em famílias) é uma possibilidade. Nessa situação, tanto a fenotipagem quanto a genotipagem são feitas a nível de família e não de indivíduo, sendo assim uma forma de redução de gastos, uma vez que grandes populações podem ser reduzidas a amostras de famílias (Rios et al., 2021).

Associações genótipo-fenótipo e análises multi ômicas

A identificação de associações genótipo-fenótipo é de suma importância tanto para programas de melhoramento quanto para investigações metabólicas/fisiológicas. Marcadores moleculares em desequilíbrio de ligação com QTL podem ser utilizados auxiliando programas de melhoramento a selecionar amostras de maior valor genético e na identificação de regiões genômicas que atuam na regulação da característica avaliada. Atualmente existem diferentes métodos, com vantagens e desvantagens, que são utilizados para identificar essas associações.

Um método tradicional é através do mapeamento de QTL, que apesar da sua importância, possui desvantagens que impedem sua aplicação constante em programas de melhoramento (Bernardo, 2008). Além da necessidade de populações biparentais segregantes (RILs, NILs, F2, etc), o alto desequilíbrio de ligação induzido nessas populações experimentais restringe a relevância dos resultados apenas à população estudada e a um número reduzido de marcadores ancorados a grupos de ligação. Ademais, o mapeamento possui melhor eficiência para características controladas por “*major-genes*”, que são incomuns para características de importância agrônômica (Mohan et al., 1997; Goddard e Hayes, 2007; Dhingani et al., 2015; Crossa et al., 2017). Outra forma de detecção de QTL é através do método de GWAS (Estudos de Associação Genômica Ampla), que apesar de assim como no mapeamento de QTL fazer uso de modelos lineares mistos para identificar as associações, não necessita de populações biparentais, podendo utilizar populações de alta diversidade para identificar as associações e os resultados não estão restritos a população estudada (Myles et al. 2009, Bernardo, 2016; Crossa et al., 2017). Porém, como nessas populações o desequilíbrio de ligação é muito menor, é necessário que as amostras sejam

genotipadas com grandes quantidades de marcadores distribuídos por todo o genoma (Zargar et al., 2015).

Apesar de não ser um método tão estabelecido como o mapeamento de QTL e o GWAS, a popularização do uso de algoritmos de aprendizado de máquina para predição genômica, fez com que os métodos de seleção de *features* passassem a ser utilizados como forma de identificar marcadores associados a fenótipos. Seleção de features é uma estratégia usada em ciência de dados para remover dados redundantes, incorretos ou irrelevantes em uma modelagem, e em alguns casos aumentar a performance do modelo (Miao & Niu, 2016; Cai et al., 2018). No contexto da predição genômica, ao selecionar os melhores marcadores para a predição, a seleção de *features* acaba por identificar um conjunto de marcadores que possivelmente estão em desequilíbrio de ligação com os QTL que influenciam o fenótipo. Essa estratégia já foi aplicada em diversas espécies, sendo capaz de aumentar a performance dos modelos, ou pelo menos manter a performance utilizando conjuntos muito menores de marcadores (Li et al. 2018; Azodi et al., 2019 ; Luo et al., 2021; Piles et al., 2021). Além disso, outros trabalhos vêm mostrando que a posição desses marcadores pode ser utilizado em investigações de processos moleculares relacionados ao fenótipo avaliado (Steinfath et al., 2010; Heer et al., 2018; Zhou et al., 2019; Aono et al., 2020; Pimenta et al., 2021; Aono et al., 2022; Pimenta et al., 2022).

Apesar da existência de diferentes métodos para estabelecer relações estatísticas entre genótipos e fenótipos, os genes, moléculas e interações moleculares envolvidas nessas relações não são explícitas e demandam diversos outros tipos de análises para serem elucidadas. Nesse sentido, a integração de dados biológicos, chamada de análises multiômicas, tem como objetivo fazer uso de informações biológicas, especialmente moleculares, de diferentes níveis metabólicos para compreender de forma sistêmica e holística processos biológicos complexos que controlam as características investigadas (Richardson, Tseng e Sun, 2016; Yan et al., 2018). Os métodos multiômicos abrangem especialmente os dados genômicos, proteômicos, transcriptômicos, metabolômicos e epigenômicos, podendo ainda ser estendido para informações biológicas mais específicas, como dados lipidômicos, fosfoproteômicos ou glicoproteômicos (Subramanian et al., 2020). A disponibilidade de dados multiômicos e métodos estatísticos apropriados para analisar e integrar esses dados tem permitido seu uso em pesquisas de diversas áreas, como em humanos, especialmente estudos de doenças (Yang et al, 2014, Vasaikar et al., 2018; Lloyd-Price et al., 2019; Hill et al., 2022), microrganismos (Borin et al, 2018; Rosolen et al, 2022), animais (Gaddis et al, 2016; Mateescu et al, 2017) e plantas, incluindo trabalhos direcionados ao melhoramento

molecular (Scossa, Alseekh e Fernie, 2021; Francisco et al., 2021; Knoch et al., 2021; Cao et al., 2022; Cardoso-Silva et al, 2022)

Considerando que nos programas de melhoramento muitas vezes são feitos trabalhos de genômica e transcriptômica, uma forma interessante de integrar esses dados é através das redes de co-expressão gênica. A capacidade das redes de simular sistemas biológicos complexos e inferir novas associações biológicas tem revolucionado a pesquisa na área (D’haeseleer et al., 2000; Liu et al., 2020). Baseado no princípio “*guilt by association*”, que no caso das redes construídas com dados transcriptômicos, constata que genes com funções biológicas correlatas tendem a interagir nas redes (Oliver, 2000; Wolfe et al., 2005; Childs et al., 2011), é possível estudar relações regulatórias, inferir vias metabólicas e fazer transferência de anotação funcional (Rao & Dixon, 2019). Em resumo, as redes são construídas considerando a correlação do nível de expressão entre dois genes em diferentes amostras, e genes com correlação acima de um limiar definido são considerados co-expressos (Rao & Dixon, 2019). Dessa forma, utilizando resultados de associações genótipo-fenótipo (QLT) obtidos através dos dados genômicos e identificando genes fisicamente ligados a esses loci, é possível isolá-los na rede junto de seus módulos de co-expressão e expandir a investigação para conjuntos gênicos que interagem e atuam na características de interesse (Francisco et al., 2021; Pimenta et al., 2022).

OBJETIVOS

Objetivo Geral

Desenvolver uma ferramenta de fácil uso para a identificação de contaminantes em populações biparentais tetra e hexaplóides e investigar vias metabólicas relacionadas a produção de biomassa e crescimento em *U. ruziziensis* através de uma abordagem multiômica integrando predição genômica e rede de co-expressão.

Objetivos Específicos

- Desenvolver uma metodologia para a identificação de contaminantes em populações biparentais tetra e hexaplóides;
- Identificar contaminantes em populações reais de forrageiras;
- Implementar a metodologia em um aplicativo com interface gráfica;
- Avaliar a aplicabilidade de predição genômica em bulks de famílias de meios irmãos;
- Comparar modelos convencionais e de aprendizado de máquina para predição genômica;
- Avaliar o uso de métodos de seleção de features para reduzir o conjunto de marcadores necessários para a predição;
- Identificar marcadores associados a características agronômicas através de sua importância para a predição;
- Montar um transcriptoma e fazer a anotação funcional dos genes;
- Identificar genes fisicamente ligados aos marcadores selecionados;
- Investigar a função dos genes identificados;
- Construir uma rede de co-expressão utilizando o transcriptoma;
- Investigar os processos biológicos relacionados aos genes previamente identificados em conjunto com genes co-expressos na rede;
- Diferenciar os processos biológicos relativos às temporadas de chuva e seca.

CAPÍTULO I

A semi-automated SNP-based approach for contaminant identification in biparental polyploid populations of tropical forage grasses.

Artificial hybridization plays a fundamental role in plant breeding programs since it generates new genotypic combinations that can result in desirable phenotypes. Depending on the species and mode of reproduction, controlled crosses may be challenging, and contaminating individuals can be introduced accidentally. In this context, the identification of such contaminants is important to avoid compromising further selection cycles, as well as genetic and genomic studies. The main objective of this work was to propose an automated multivariate methodology for the detection and classification of putative contaminants, including apomictic clones (ACs), self-fertilized individuals, half-siblings (HSs), and full contaminants (FCs), in biparental polyploid progenies of tropical forage grasses. We established a pipeline to identify contaminants in genotyping-by-sequencing (GBS) data encoded as allele dosages of single nucleotide polymorphism (SNP) markers by integrating principal component analysis (PCA), genotypic analysis (GA) measures based on Mendelian segregation, and clustering analysis (CA). The combination of these methods allowed for the correct identification of all contaminants in all simulated progenies and the detection of putative contaminants in three real progenies of tropical forage grasses, providing an easy and promising methodology for the identification of contaminants in biparental progenies of tetraploid and hexaploid species. The proposed pipeline was made available through the polyCID Shiny app and can be easily coupled with traditional genetic approaches, such as linkage map construction, thereby increasing the efficiency of breeding programs.

INTRODUCTION

The concept of artificial crossings to generate experimental plant populations was introduced scientifically in the historical work of Mendel (1866) and became a fundamental tool for genetics studies and breeding programs, maximizing genetic gains by the selection of superior genotypes (Bourke et al., 2018). Although this concept is well-known and applied in important crops (Goulet et al., 2017), there are few commercial cultivars of tropical forage grasses originating from artificial hybridization (Azevedo et al., 2019). Perennial tropical forage grasses are recognized worldwide for their economic importance as food for beef and dairy cattle in the tropical and subtropical regions (Pereira et al., 2018a; ABIEC, 2020). In addition to the recently initiated breeding programs and long selection cycles, some intrinsic biological characteristics, including different reproductive modes (sexual and facultative apomixis), levels of ploidy, and self-incompatibility (SI) within and between the species, are challenges faced by breeders when performing controlled crosses using these plants (Lutts et al., 1991; Jank et al., 2011; Pereira et al., 2018a; Worthington et al., 2019).

Apomixis is a type of asexual reproduction through seeds that produces a progeny which is genetically identical to the maternal plant (Bicknell, 2004; Hand and Koltunow, 2014). Thus, to explore the genetic diversity of polyploid apomictic forage grasses, controlled crosses are performed between sexual and apomictic (pollen donor) parents with contrasting traits and the same ploidy level. In most species, the ploidy of the sexual plants does not match with the ploidy of the apomictic plants; this way, it is necessary the artificial polyploidization (usually chromosome duplication) of the sexual ones to perform the crosses at the same ploidy level (Pinheiro et al., 2000; Simioni and Valle, 2009; Acuña et al., 2019). However, because of the reproductive system of these plants, during the crosses, some individuals are also generated by foreign pollen or by self-fertilization of female parents. Some of these scenarios can also occur in other species, such as sugarcane, eucalyptus, sainfoin, and lettuce (Santos et al., 2014; Subashini et al., 2014; Kempf et al., 2015; Patella et al., 2019). Also, if facultative apomictic plants (i.e., apomictic plants in which sexual reproduction events are also observed) are used as females, they simultaneously generate hybrid by crossings and clones by apomixis (Smith, 1972). Contamination by physical admixture during seed harvesting and handling is also possible, especially when crosses are performed in the field, as these species are mostly anemophilous

(i. e., the pollination of these species occurs by the wind) (Bateman, 1947; Simeão et al., 2016a). In this context, it is evident that controlled crosses may not avoid contamination, compromising the attainment of pure hybrid progeny and, consecutively, unbiased genetic and genomic methods, such as segregation tests, linkage map construction, quantitative trait locus (QTL) mapping and linkage disequilibrium analysis, which are fundamental for understanding the genotype and its relationship to the phenotype (Kemble et al., 2019).

Traditionally, hybrid identification has been performed on the basis of morphological traits and microsatellite markers (Santos et al., 2014; Jha et al., 2016; Zhao et al., 2017; Patella et al., 2019). However, both methodologies have disadvantages. Morphological traits are time-consuming and have low throughput, with accuracies influenced by environmental factors (Zhao et al., 2017), while developing microsatellite markers is an expensive and time-consuming process that requires previously obtained genomic sequence information and investment in terms of designing locus-specific primers and optimizing PCR conditions (Vieira et al., 2016). Moreover, size estimates across alleles at each locus are imprecise, especially in polyploids, such as tropical forage grasses, leading to frequent genotyping errors (Guichoux et al., 2011; Hodel et al., 2016). Therefore, there is a need to develop alternative methodologies using molecular markers to quickly and efficiently distinguish true hybrids resulting from the breeding program crosses from those resulting from accidental selfing or contamination in biparental populations.

Single nucleotide polymorphism (SNP) markers have been shown to be an excellent tool for genomic studies in function of their high-throughput nature, low error rates, and abundance in eukaryote genomes (Helyar et al., 2011). Additionally, genotyping methodologies based on next-generation sequencing (NGS), such as genotyping-by-sequencing (GBS) proposed by Elshire et al. (2011) and Poland et al. (2012), have been demonstrated to be quick, affordable, and highly robust for discovering and profiling a large number of SNP loci, even in species with no genomic information available and large genomes, such as polyploids (Elshire et al., 2011; Poland et al., 2012; Ferreira et al., 2019; Deo et al., 2020; Mollinari et al., 2020). In the last few years, many studies using SNP markers in tropical forage grasses, mainly coupled with principal component analysis (PCA) to investigate the structure of the progenies and remove putative contaminants, have been published (Lara et al., 2019; Deo et al., 2020; Zhang et al., 2020). Even though PCA can be used to retain and explore most of the variations in large SNP datasets through the first principal components (PCs) (Jolliffe and Cadima, 2016), such a multivariate technique is not appropriate for contaminant identification, which requires more specific approaches, such as pedigree reconstruction, sibship and parentage assignment.

The different methods for identifying the parents of a progeny are based on exclusion (Zwart et al., 2016; McClure et al., 2018), likelihood-based (Spielmann et al., 2015), and Bayesian (Christie et al., 2013) techniques, using Mendel's laws to infer relationships between samples through genotyped loci (Thompson, 1975; Thompson and Meagher, 1987). This evaluation is generally

Abbreviations: AC, Apomictic clone; CA, Clustering analysis; FC, Full contaminant; GA, Genotype analysis; GBS, Genotyping-by-sequencing; HP, Hybrid progeny; HS, Half-sibling; IBD, Identity-by-descent; MRAC, mean rate of ACs correctly identified; MRC, Mean rate of contaminants (correctly identified); MRCC, Mean rate of cross-contaminants (HSs/FCs) correctly identified; MRH, Mean rate of hybrids correctly identified; MRSP, Mean rate of SPs correctly identified; NIPALS, Non-linear iterative partial least squares; NGS, Next-generation-sequencing; P1/Parent 1, Female parent for simulated or real population; P2/Parent 2, Male parent for simulated or real population; PC, Principal component; PCA, Principal component analysis; PCR, Polymerase chain reaction; QTL, Quantitative trait loci; RAPD, Random amplified polymorphic DNA; SNP, Single nucleotide polymorphism; SP, Self-fertilization progeny of one of the parents; SSR, Simple sequence repeats.

based on pairwise Mendelian segregation tests, comparing individuals and generating different measures that account for the similarity between a sample and one of the parents or for a rate of unexpected genotypes in each sample considering the genotypes of both parents. Therefore, such genotype analyses (GAs) can be used to define what is not genotypically similar and consecutively represents an experimental contaminant. In this work, we propose to use GA measures for performing clustering analyses (CAs) and automatically identifying contaminants in forage grass biparental populations, grouping individuals based on GA similarity measures instead of their raw SNP data. Although CA of large SNP datasets has been extensively used to discover patterns in population relatedness and structure (Gori et al., 2016; Muniz et al., 2019; Yousefi-Mashouf et al., 2021), its use for parentage assignment is not common because of the non-specificity and constancy of the clusters, but has already been combined with previously described techniques for parentage and sibship inference in diploids (Ellis et al., 2018).

Instead of relying strictly on PCA for population analyses and *ad hoc* decisions (Deo et al., 2020; Zhang et al., 2020), we created an semi automated pipeline, combining GA and CA that allow us not only to precisely identify but also to list the types of contaminants in a biparental cross. For this purpose, we simulated several biparental progenies with contaminants to (1) identify dispersion patterns in a PCA biplot that can suggest the presence of contaminants, (2) create appropriate GA measures for contaminant identification in polyploid forage grass samples, generating scores for all individuals, and (3) integrate such scores in an automatic CA to separate the real hybrids from the contaminants. These steps led to the formulation of a unified methodology, which we applied to biparental progenies of three different species of tropical forage grasses: *Megathyrsus maximus* (Jacq.), syn. *Panicum maximum* Jacq. (B. K. Simon & S. W. L. Jacobs), *Urochloa decumbens* (Stapf), syn. *Brachiaria decumbens* Stapf (R. D. Webster) and *Urochloa humidicola* (Rendle), syn. *Brachiaria humidicola* (Rendle, Schweick) (Morrone and Zuloaga, 1992; Torres-González and Morton, 2005). The implemented pipeline was made available through a Shiny app and has a high potential to be employed in pre-breeding stages, as well as in genomic studies involving polyploid biparental progenies in general.

MATERIALS AND METHODS

The following sections describe the steps involved in the generation of real and simulated data and their use to propose a methodology for contaminant identification in biparental crosses. First, the genotyping and allele dosage estimation for biparental F_1 populations of three tropical forage species are presented (2.1, 2.2, and 2.3). Then, different biparental crossings are simulated (2.4). Finally, contaminant identification methodologies are applied to the simulated and real data (2.5, 2.6, 2.7, and 2.8).

Plant Material

Genotypic data were obtained from biparental F_1 progenies of *Urochloa humidicola* (a segmental allopolyploid, with $2n = 6x$

$= 36$), *Urochloa decumbens* (a segmental allopolyploid, with $2n = 4x = 36$), and *Megathyrsus maximus* (an autopolyploid, with $2n = 4x = 32$), three important species of tropical forage grasses used in the pastures of tropical and subtropical areas. All these intraspecific crossings were performed by the Brazilian Agricultural Research Corporation (Embrapa) Gado de Corte, located in Campo Grande, Mato Grosso do Sul, Brazil ($20^\circ 27' S$, $54^\circ 37' W$, 530 m), and are part of the breeding programs of this research institution. Details about the crossing were described by Deo et al. (2020) for *M. maximus* and by Barrios et al. (2013) for *U. decumbens*. For *U. humidicola*, the crossings were manually performed in controlled crosses in greenhouses at Embrapa. Plants from the male genitor were cultivated in the field and pollen grains were collected in the day of the crossings or in the day before and stored overnight in a Petri plate in a refrigerator. Plants from the female genitor were cultivated in pots in the greenhouse and the inflorescences had the spikelets at anthesis removed with a tweezer, only those remaining spikelets were going to be opened in the next day. At the crossing day, the spikelets at anthesis were pollinated with the collected pollen grains and the inflorescences were covered with a paper bag and identified. After dehiscence, the F_1 seeds were collected and processed until germination in trays and then planted in the field in single plots.

The *U. humidicola* progeny consisted of 279 hybrids obtained from a cross between the sexual accession H031 (CIAT 26146) and the apomictic cultivar *U. humidicola* cv. BRS Tupi, as described by Vigna et al. (2016). The cross between *U. decumbens* D24/27 (sexual diploid accession tetraploidized by colchicine) and the apomict *U. decumbens* cv. Basilisk generated a progeny with 239 hybrids (Ferreira et al., 2019). Finally, the progeny of *M. maximus* included 136 hybrids originating from a cross between the sexual genotype S10 and *M. maximus* cv. Mombaca (apomictic parent) (Deo et al., 2020). The apomixis in the cultivars BRS Tupi, Basilisk, and Mombaca is of the pseudogamic aposporic types.

Genotyping-By-Sequencing Library Preparation

Genotyping-by-sequencing (GBS) libraries of the *U. decumbens* and *M. maximus* progenies were built and sequenced as described by Ferreira et al. (2019) and Deo et al. (2020), respectively. For the progeny of *U. humidicola*, DNA was extracted following Vigna et al. (2016), and the GBS libraries were built according to Poland et al. (2012), containing five replicates for each parent and one for each hybrid. Genomic DNA (210 ng of DNA per individual) was digested using a combination of a rarely cutting enzyme (PstI) and a frequently cutting enzyme (MspI). Subsequently, the libraries were sequenced as 150-bp single-end reads using the High Output v2 Kit (Illumina, San Diego, CA, USA) in the NextSeq 500 platform (Illumina, San Diego, CA, USA). The quality of the resulting sequence data was evaluated using the FastQC toolkit (<http://www.bioinformatics.babraham.ac.uk/projects/fastqc/>).

GBS-SNP Discovery and Allele Dosage

We analyzed the raw data of the three biparental progenies using the Tassel-GBS pipeline (Glaubitz et al., 2014) modified for polyploids (Pereira et al., 2018b), which considers the original read depths for each SNP allele. The Bowtie2 algorithm version 2.1 (Langmead and Salzberg, 2012) was used to align the reads of the *Urochloa* spp. and *M. maximus* against the reference genomes of *Setaria viridis* v1.0 and *Panicum virgatum* v1.0, respectively, since the reference genomes are not available for the species under study. In this stage, a limit of 20 dynamic programming problems (D), a maximum of four times to align a read (R), and a very-sensitive-local argument were considered. Both genomes used as references were retrieved from the Phytozome database (Goodstein et al., 2012).

For quality purposes, the SNPs were submitted to a filtering procedure using VCFtools (Danecek et al., 2011), with the following parameters: maximum number of alleles of two (to include only bi-allelic loci), maximum missing data per marker of 25%, and minimum read depth per individual of 20 reads for *M. maximus* and *U. decumbens*, and 40 reads for *U. humidicola*. Due to the polyploid nature of the species, a high sequence depth is required to identify the genotypic class accurately (Cappai et al., 2020; Ferrão et al., 2020; Mollinari et al., 2020), and even higher values were used for *U. humidicola* because it is a hexaploid. Finally, the Updog R package (Gerard et al., 2018) was used to estimate the allele dosage of each SNP locus, with a fixed ploidy parameter of four for *M. maximus* and *U. decumbens*, and six for *U. humidicola*. The flexdog function was used with the “fl” population model for the three populations. The posterior proportion of mis-genotyped individuals (prop_mis) was set at six different values (0.05, 0.1, 0.15, 0.20, 0.25, and 0.3) for *M. maximus* and *U. decumbens*, aiming to compare the rates of the tetraploid dosages in the parents and assess the influence of the number and quality of the markers in further analysis. For the hexaploid population of *U. humidicola*, prop_mis was set at 0.2.

The genotyping data were organized into marker matrices $M_{(n \times m)}$, where n denotes the samples, m denotes the markers, and the allele dosage genotypes are encoded as 0, 1, 2, 3, 4, 5, or 6 for nulliplex, simplex, duplex, triplex, quadruplex, quintuplex, and hexaplex data, respectively.

Simulated Data

Biparental F_1 populations were simulated using the PedigreeSim R package (Voorrips and Maliepaard, 2012), a software package that simulates meiosis and uses this information to create cross populations in tetraploid species. To create the linkage map required by PedigreeSim, the previously published map for *M. maximus* (Deo et al., 2020) was used as a model to estimate the main parameters, such as the number and size of chromosomes, density, gap regions, and centromere position. Eight chromosomes with sizes between 90 and 120 centimorgans (cM) and 600–900 SNP markers per chromosome, both randomly sampled, were created. In addition, the markers were considered to be distributed along the chromosomes with a minimum distance between adjacent markers of 0.1 cM. The centromere position was sampled between 10 and 50 cM, preferential pairing was set to zero, and the quadrivalent

fraction was set for natural pairing. In this case, the fraction of quadrivalents arises automatically from the pairing process at the telomeres. Other options of the software were kept as default. All these files were created using R software (R Core Team, 2020).

To perform the crosses, four parents (P1, P2, P3, and P4) were created, and the genotypes of these parents were simulated based on the rate of allele dosages of parents genotyped in real biparental progenies: P1 and P2 from *M. maximus* (Deo et al., 2020) and P3 and P4 from *U. decumbens* (Ferreira et al., 2019). Considering these rates, the haplotypes of each of the four homologous chromosomes were randomly created for each parent. The simulated crosses between these parents were based on the following combinations: $P1 \times P2$, $P1 \times P1$ (self-fertilization), $P1 \times P3$, $P1 \times P4$, and $P3 \times P4$, with a progeny size of 200.

The results of the simulated crosses were converted into marker matrices (M), and all subsequent manipulations were performed using R software (R Core Team, 2020). To insert genotyping errors, 5% of the genotypes were randomly replaced by other genotype values with equal probability, and between 1 and 5% of the genotypes of each marker were removed to simulate the missing data (NAs). Clonal individuals were simulated by duplicating the genotype of a parent, and errors and NAs were inserted as described above.

Using the tetraploid populations created in the PedigreeSim software, four scenarios were established to analyze the different types of contaminants that could occur in biparental populations of tropical forage grasses. The first two scenarios were represented by contaminants resulting from the reproductive mode of parents, which can reproduce by (1) apomictic clones (ACs), or (2) self-fertilization progeny of one of the parents (SPs), resulting in segregating individuals. The last two scenarios represent (3) cross-contamination, that is, when fertilization occurs by foreign pollen, resulting in half-siblings (HSs), or (4) when physical mixtures occur during seed handling, resulting in full contaminants (FCs). In each of the four possible scenarios, the size of the base population was 200 hybrids (HPs), and the HPs were progressively replaced by contaminants until 25% of the samples were contaminants. In addition, to investigate a joint scenario with four parents (P1, P2, P3, and P4) with AC and SP contamination, a population of 1,200 individuals (200 P1-ACs, 200 P1-SPs, 200 HPs from $P1 \times P2$, 200 HPs from $P1 \times P3$, 200 HPs from $P1 \times P4$, and 200 HPs from $P3 \times P4$) was created. These described populations were constructed to investigate how contaminants influence principal component analysis (PCA) scatter plot dispersion patterns.

For the evaluation of the proposed contaminant identification method, 6,000 populations were simulated. Each one was composed of 200 individuals with a random number of contaminants, ranging between 1 and 50 and distributed per contaminant type considering random probabilities between 0.1 and 0.8. The populations were divided into six equal size groups according to the number of genotyped markers. Considering n as the total simulated markers, the groups were composed of: $n/2$, $n/4$, $n/8$, $n/16$, $n/32$, and $n/64$ markers. For each population, the subset of markers used was randomly sampled from the total simulated markers. Furthermore, a biparental population with

200 individuals [150 HP ($P1 \times P2$), 10 AC ($P1$), 10 SP ($P1$), 10 HS1 ($P1 \times P3$), 10 HS2 ($P1 \times P4$), and 10 FC ($P3 \times P4$)] was also simulated to exemplify the use of GA and CA in the contaminant identification.

Principal Component Analysis

Principal component analyses were performed by the R package *pcaMethods* (Stacklies et al., 2007) using the non-linear estimation by iterative partial least squares (NIPALS) algorithm (Wold and Krishnaiah, 1966) to calculate the eigenvalues with missing data imputation. Given a matrix $X_{m,n}$ representing the n random variables (herein SNPs) across m individuals, this analysis transforms X by multiplying it by the orthogonal eigenvectors, generating a matrix $X_{m,p}$ of new p variables [the principal components (PCs)] with specific mathematical properties (Maćkiewicz and Ratajczak, 1993). The *ggplot2* R package (Wickham and Chang, 2016) was used to construct scatter plots of the first two PCs. These graphical visualizations were used to identify clustering patterns that may be associated with contaminants in the progeny.

Genotypic Analysis

The term genotypic analysis (GA) is employed here to refer to an analysis that evaluates all the samples of a progeny considering what is genotypically expected for a contaminant. Three different measures were created for evaluating the samples: GA-I for AC identification and GA-II for SP identification, both accounting for a similarity rate between the sample and one of the parents (computed separately for each), and GA-III, accounting for a rate of unexpected genotypes in each sample considering the genotypes of both the parents, enabling the identification of half-siblings (HSs) and full contaminants (FCs) in the progeny.

To investigate whether an individual x is an AC of a parent p , the GA-I scores were calculated using the marker matrix M with n rows (individuals) and m columns (markers). Then, the similarity between x and p was the proportion of allele dosages in $M_{x,i}$ that satisfied the condition, $M_{x,i} = M_{p,i}$ with $1 \leq i \leq m$. This measure is based on the presumption that, given Mendel's law, each individual inherits genetic material from its parents (Mendel, 1866; Miko, 2008). However, if one of the parents reproduces through apomixis, a genetically identical progeny is produced (Hand and Koltunow, 2014). Therefore, in a suite of Mendelian loci, if a putative individual shows a high similarity (GA-I close to 1.00) with one of the parents, it can be considered a clone of this parent.

In the case of SP samples, the GA-II scores were calculated by computing the similarity between the progeny samples and the parents considering only nulliplex allele dosages; i.e., for a parent p and an individual x , GA-II was the proportion of allele dosages in $M_{x,i}$ (with $1 \leq i \leq m$) that satisfied $M_{x,i} = M_{p,i} = 0$. If a parent reproduces through self-fertilization, Mendelian segregation should be observed. Using a tetraploid species as an example, a parent with the genotype AABB at a specific locus, after self-fertilization, would generate a progeny with genotypes in all possible doses (AAAA, AAAB, AABB, ABAB, and BBBB) (Hackett et al., 2013). However, if we focus only on the markers

for which the parent had a nulliplex genotype (AAAA), the progeny produced would be genetically identical to the parent at those loci. Thus, GA-II computes a similarity rate between the sample and the parent considering only those markers; in this situation, it was expected that SP contaminants would present GA-II scores close to 1.00.

For the HSs and FCs, the GA-III term calculates the rate of unexpected allele dosages for the progeny individuals across all the markers. Considering the combination of gametes for parent $p1$ and $p2$ at a SNP i with $1 \leq i \leq m$, the GA-III of an individual x is the proportion of unexpected allele dosages for its set of markers. Considering the allele dosage of each parent at each marker, it is possible to define which dosage is not expected in their progeny. For example, if one parent is nulliplex (AAAA) for a marker and the other is simplex (AAAB), the gametes produced by the nulliplex are all AA, and for the simplex, they can be AA or AB (Hackett et al., 2013). Their combination can produce a progeny with only nulliplex or simplex for this marker, and the presence of other dosage types is an evidence for the fact that this individual may not belong to the cross. In this way, for all markers, GA-III tested whether the genotype of this sample was expected considering both parental genotypes, computing a rate of unexpected genotypes for each sample (Supplementary Table 1). In this analysis, it was expected that HSs and FCs would show higher GA-III scores than HPs, enabling their identification.

Clustering Analysis

The contaminant identification process is based on a clustering analysis (CA) performed using an average linkage hierarchical clustering approach with R software (R Core Team, 2020). Considering the GAs calculated, pairwise Euclidean distances between these values were calculated across the progeny and were used to obtain 27 different clustering indexes (Supplementary Table 2) with numbers of clusters varying from 2 to 15, implemented in the R package *NbClust* (Charrad et al., 2014). The package automatically calculates the indexes, defines the best clustering scheme based on majority rule (i.e., most indicated number of clusters), and classifies the samples into clusters.

Contaminant identification was then performed with the best clustering configuration scheme. Individuals in groups separated from most of the population were considered contaminants and classified according to the following rules applied to the GA measures within these clusters: (1) individuals within a cluster having the greatest GA-I values for one parent were considered ACs when the median of these measures was >0.75 ; (2) individuals within a cluster with the median GA-II values for one parent >0.75 and not belonging to Group (1) were considered SPs; and (3) individuals not belonging to Groups (1) and (2) and with a within-group minimum GA-III value greater than the maximum measure of the group with the minimum GA-III median were considered HSs/FCs. Therefore, in a simplified and automated process with only the threshold of GA measures as an *ad hoc* decision, we obtained the final data set with parents and their corresponding true hybrids.

The method was evaluated on a set of 1,000 simulated populations, computing the following metrics considering the most indicated clustering scheme: mean rate of hybrids correctly identified (MRH), mean rate of contaminants correctly identified (MRC), mean rate of apomictic clones correctly identified (MRAC), mean rate of SPs correctly identified (MRSP), and mean rate of cross-contaminants (HSs/FCs) correctly identified (MRCC). Furthermore, the same metrics were computed considering the three most indicated clustering schemes; in this situation, the highest rate among the three schemes for each simulated population was used to calculate the mean.

Contaminant Identification in Real Data

Combining GA, CA, and PCA, we established a four-step contaminant identification methodology as follows, and applied it to the real populations (Figure 1, Part III Contaminant Identification):

1. Construction of a scatter plot with the first PCs from a PCA performed with the SNP data organized according to allele dosage, looking for evidence of contaminants in the population. When no contaminants are detected, simulated clones (25% of the population) from one of the parents can be artificially added to the population, changing the dispersion pattern of individuals and inducing contaminant separation;
2. Calculation of five different GA measures for each individual (GA-I and GA-II, considering Parents 1 and 2, respectively, and GA-III). GAI and GAII were calculated in the same way for all ploidy, but for hexaploid progeny, GAIII was adapted considering its respective segregation;
3. Performance of CA using the GA data to identify clusters in the population;
4. Visual inspection of the histograms, to classify the clusters according to the GA value differences described in section Clustering analysis. This step is done in a sequential process, in which the first ACs are identified and removed, then SPs, and lastly, HSs/FCs are identified and removed.
5. Recalculation of PCA to confirm in the biplot the expected dispersion pattern of a population with no contaminants.

All these procedures were unified in polyCID Shiny app, created using R software together with the libraries shiny (Chang et al., 2021), shinydashboard (<https://cran.r-project.org/web/packages/shinydashboard/index.html>), and DT (<https://cran.r-project.org/web/packages/DT/index.html>). polyCID is an R-Shiny Web graphical user interface (GUI) that combines all the described analyses in a simple way and provides a user-friendly tool, fully available and documented at <https://github.com/lagmunicamp/polycid>.

RESULTS

The results are organized as follows. First, the genotyping and allele dosage information for the three biparental progenies of the tropical forage species is presented (3.1). Next, the application of principal component analysis (PCA) to the simulated data is shown (3.2). Then, the use of GA and CA in contaminant identification in the simulated data is described (3.3), and finally,

the results obtained from the contaminant identification in real data are presented (3.4). Furthermore, for simulated and real populations, P1/Parent 1 is the female parent and P2/Parent 2 is the male parent.

GBS-SNP Discovery and Allele Dosage Estimation

After SNP calling using the Tassel- genotyping-by-sequencing (GBS) pipeline (Glaubitz et al., 2014) modified for polyploids (Pereira et al., 2018b), filtering markers for missing data (NAs) and read depth with VCFtools (Danecek et al., 2011), we obtained 15,279 SNP markers for *Urochloa humidicola*, 8,036 for *Urochloa decumbens*, and 6,337 for *Megathyrsus maximus*. Three individuals ("Bh181," "Bh226," and "Bh245") of the *U. humidicola* progeny were removed because of the high content of missing data (>44%).

The Updog R package (Gerard et al., 2018) was used to estimate the allele dosage for the SNP loci identified in each progeny. For the six values of prop_mis used (0.05, 0.10, 0.15, 0.20, 0.25, and 0.30), 4,003, 5,179, 5,863, 6,068, 6,161, and 6,215 markers were obtained for *M. maximus* and 1,195, 1,745, 2,303, 2,862, 3,165, and 3,243 markers were obtained for *U. decumbens*, respectively, while 7,253 markers were obtained for *U. humidicola* using a prop_mis value of 0.20.

Principal Component Analysis

Marker matrices of each simulated scenario were used to perform a PCA, looking for patterns spanned by the first two PCs that can aid in the identification of contaminant samples. Details of these simulated scenarios, such as the size of chromosomes, position of centromeres, and the number of markers can be found in **Supplementary Tables 3–5**. The PCA scatter plot of the simulated population without contaminants had hybrids and parents distributed with no apparent clustering patterns among the individuals, with 4% of variance explained by the first two principal components (PCs) (**Supplementary Figure 1**).

The same biplot distribution was observed when only one contaminant was added to the biparental population, i.e., an apomictic clone (AC) (**Figure 2A**), self-fertilization progeny (SP) (**Supplementary Figure 2**), half-sibling (HS) (**Supplementary Figure 3**), or full contaminant (FC) (**Supplementary Figure 4**). In these situations, the genetic variation related to contamination could not be detected by the first components and therefore assessed by visual inspection. When the number of contaminants was progressively increased in the scenarios, the dispersion pattern of the scatter plots began to reveal the separation of the contaminants from the hybrids. For the scenarios, five (**Figure 2B**), four (**Supplementary Figure 5**), six (**Supplementary Figure 6**), and three (**Supplementary Figure 7**) contaminants were necessary to clearly visualize the separation. Adding these contaminants changed the source of variation in the first PCs, which changed little (<0.2%). As the number of contaminants increased to 25% of the population, it was possible to observe in the PCA biplot that the hybrids were projected between the parents, the ACs/SPs were closer to the parent of origin (**Figure 2C** and **Supplementary Figure 8**), the HSs/FCs formed separated groups

(Supplementary Figures 9, 10), and the sums of variance in the first two PCs changed to values between 10.8 and 17%.

Considering that the analysis of the first two PCs through a PCA scatter plot could not reveal contaminants at low frequencies, biparental populations with 199 HPs and one contaminant were simulated, and 50 ACs (25%) of one of the parents were included. This unique contaminant may be an SP (Scenario 2), AC (Scenario 3), or FC (Scenario 4). As a result, we observed that the inclusion of these simulated clones, which occurs in real populations, changed the sums of variance in the first two PCs to a value of $\sim 10.3\%$ and increased the dispersion pattern in the PCA scatter plot, leading to the formation of different subgroups that allowed for the visualization of SP or HS contaminants (Supplementary Figures 11, 12). On the other hand, FCs and HPs were grouped together and could not be identified visually in the scatter plot (Supplementary Figure 13).

Finally, when simulating an open pollination population with four different possible parents, the biplot of the PCs was able to provide visual separation of the different progenies. It was possible to identify each cross since HPs formed a subgroup between their respective parents. In addition, the AC and SP contaminants grouped together with their parents (Figure 3).

Semi Automatic Contaminant Identification

To look for the patterns in contaminant genotype analyses (GA) measures, the three described GAs were calculated in a simulated population of 200 samples composed of 150 hybrids (HPs) and 50 contaminants (10 ACs, 10 SPs, 10 HS1s, 10 HS2s, and 10 FCs); thus, five different values for each putative

hybrid were generated. We analyzed how GA histograms behave for each type of contamination. In Figure 4A, AC individuals formed a group with the greatest GA-I scores for Parent 1 (red circle) and were removed to analyze the other histograms. In the same way, the GA-II histogram (Figure 4B) showed that the SP samples had the highest scores for Parent 1 (red circle), and these individuals were also removed. We believe that mutations, missing data, and sequencing/genotyping errors are events responsible for the differences between the expected scores (pretty close to 1) and the observed (about 0.8 to 0.9). Finally, in Figure 4C, the GA-III histogram showed that the HP samples had lower scores than the HS and FC contaminants. For a correct hybrid definition, these contaminants were also removed to generate a proper hybrid data set.

By using the idea underlying these visual histogram inspections, we implemented on GA measures a clustering-based approach for automatic contaminant identification. The established methodology employs a single hierarchical clustering algorithm on a different range of cluster numbers, defining the best clustering scheme with 27 clustering indexes (Supplementary Table 2). Employing this approach on the simulated population previously described, we observed that the defined CA separated the samples into six different groups: one for the HP and five for each type of contaminant, exactly corresponding to the simulated categories (Figure 4). Therefore, we evaluated its accuracy on additional 6,000 simulated populations and checked its appropriateness using six set sizes of markers in a broad range of possible contamination scenarios. The sets were of the following sizes: 2,758, 1,379, 689,

344, 172, and 86 markers. For each marker's set size of the, 1,000 populations were simulated sampling markers from a total of 5,516.

The mean rate of hybrids (MRHs) correctly identified was 100% for all sets of markers, except for the smallest one (86 markers), which had a slight reduction. On the other hand, the mean rate of contaminants (MRC) was around 90% for the three largest sets (2,758, 1,379, and 689 markers), which started decreasing, reaching the value of 48% in the smallest one (Figure 5A). It was possible to observe that the methodology failed only for the smallest set (86 markers), in which a true hybrid was considered a contaminant, but it rarely discarded reliable data. Regarding the contaminant classification and considering the largest sets of markers, 69, 72, and 84% were observed for the mean rate of apomictic clone (MRAC), mean rate of self-fertilization progeny (MRSP), and mean rate of cross-contaminants correctly identified (MRCC), respectively. Then, we observed a slight reduction in the 689 markers set, which showed values of 63% (MRAC), 66% (MRSP), and 76% (MRCC), followed by 49% (MRAC), 50% (MRSP), and 15% (MRCC) in the smallest set (Figure 5A).

In the function of these modest values, we also evaluated the method efficiency on the second and third best clustering configurations identified by the calculated indexes. Considering the best group separation within these three possible configurations also noticed in GA histograms, we achieved a performance improvement in all set markers, reaching an approximate accuracy of 100% in the three largest sets for all types of samples. Next, we observed a slight reduction (to values higher than 90%) in the set of 344 markers, and more prominent

reductions in the two smallest sets, reaching the values of 49% (MRAC), 85% (MRSP), and 40% (MRCC) (Figure 5B). These findings suggest that, in real applications, such evaluations in these three cluster configurations may represent an additional step for increasing the method's reliability.

Contaminant Identification in Real Populations

After investigating with simulated populations, the proposed methodology was applied to real genotyping data from three biparental *F*₁ progenies of tropical forage grasses. For the progeny of *M. maximus*, the PCA plots with different values of prop_mis showed similar sample dispersion patterns and a reduction in variance explained by the first two PCs from 10.1 to 7.5% as the number of markers increased. Therefore, the dataset obtained with the default value of prop_mis = 0.20 was used in the further analysis. Even though there was no clear group formation in the PCA scatter plot, the pattern of parents on the opposite sides and HPs grouped between them provided evidence for the presence of contaminants (Supplementary Figure 14A). Similarly, in the PCA with simulated ACs, these two individuals remained close to Parent 2 (*M. maximus* cv. Mombaça) (Supplementary Figure 14B).

The clustering analysis (CA) with GA revealed two clusters in the *M. maximus* progeny, with 134 and two samples. The GA-I histogram for Parent 2 (*M. maximus* cv. Mombaça) showed that the cluster with two samples had high scores and must be considered putative ACs of Parent 2 (*M. maximus* cv. Mombaça) (Supplementary Figure 15A). On the other hand, GA II and

III showed no evidence for other types of contaminants in the *M. maximus* progeny (Supplementary Figures 15B,C). The exclusion of these two individuals resulted in a PCA scatter plot with the expected pattern (Supplementary Figure 14C).

For the progeny of *U. decumbens*, the PCA biplots for the different values of prop_mis showed different sample dispersion patterns (data not shown). As this is a very intuitive measure for the quality of SNPs when estimating allele dosage (Gerard

et al., 2018), we chose to be conservative and used the most restrictive filter, 0.05, ensuring the selection of markers with high quality. The first PCA scatter plot showed strong evidence of contaminants in the population (Figure 6A). The algorithm found three clusters with 184, 49, and 3 samples. In the GA histograms, both Clusters 2 and 3 had high GA-I scores for Parent 2 (*U. decumbens* cv. Basilisk), providing evidence that those samples were putative ACs of this parent (Figure 7A).

The other GA histograms showed no clear evidence of other contaminants (Figures 7B,C), except two individuals that could be considered suspicious in GA-II. In this case, we followed the clustering results and did not consider these individuals as contaminants. But this is an *ad hoc* decision, so the user can choose to be conservative and remove outliers. Once again, after the elimination of these ACs, the PCA scatter plot showed the expected pattern for progeny without contaminants (Figure 6B).

For the hexaploid biparental population of *U. humidicola*, the scatter plot of the first PCs showed strong evidence for the presence of AC and/or SP contaminants (Supplementary Figure 16A). The clustering analysis of the GA scores separated the progeny into two clusters with 211 and 65 samples. The histogram of GA-I for Parent 1 (*U. humidicola* H031) showed that the cluster with 65 samples had scores close to 1.0 (Supplementary Figure 17A), representing putative ACs of the respective parent. GA-II and GA-III showed no evidence of contaminants (Supplementary Figures 17B,C). Finally, the PCA without the previously identified contaminants also showed the expected pattern for progeny without contaminants (Supplementary Figure 16B).

The PolyCID Shiny App

Finally, we implemented the polyCID Shiny app, a Web graphical user interface (GUI) that provides all previously described analyses in a user-friendly tool that allows users to identify

contaminants in biparental progeny in a simple way. The polyCID is completely R based, easy to install and presents a graphical interface designed for non-expert users, with several functions for interactive visualization of the results. The package accepts SNP data in the form of marker matrices with allele dosage information, loads this information, and performs the four-step contaminant identification methodology, as described in section Contaminant identification in real data. The Shiny-based GUI is included in the package as a standalone application, available at <https://github.com/lagmunicamp/polycid>.

DISCUSSION

Experimental populations used in the breeding programs are usually derived from a controlled cross between two or more parents, but depending on the field experiment, the species analyzed, and its reproductive biology, individuals may be generated from the mixtures of seeds, foreign pollination during open pollinated crosses, self-fertilization, or apomixis by one of the parents during the crosses. The non-identification of these contaminant individuals can interfere not only in the selection cycles of breeding programs (Telfer et al., 2015) but also in the studies of genetic diversity (Ji et al., 2013), population structure (Alam et al., 2018), linkage mapping (Deo et al., 2020), and association mapping (Lauco et al., 2018), since it can generate biased results.

In most available studies, the identification of contaminants involved the use of microsatellites and morphological markers, but this strategy can be costly and time-consuming (Santos et al., 2014; Jha et al., 2016; Zhao et al., 2017; Patella et al., 2019), especially for polyploid species. In these cases, progeny evaluation is often performed using few microsatellite markers in polyacrylamide gels, and frequently, other analyses are needed, such as genetic distance analysis (Santos et al., 2014). The low number of microsatellite markers, usually in the tens or hundreds, may prevent the identification of contaminants. Considering this scenario, we used genotyping-by-sequencing (GBS) (Poland et al., 2012) to identify thousands of single nucleotide polymorphism (SNP) markers with allele dosage information and to propose a methodology that facilitates the identification of contaminants in biparental crossbreeding of

polyploid species. Despite the emergence of several pipelines for the analysis of GBS data in polyploids, the application of these markers in parentage analysis is still little explored.

Currently, several software packages can deal with genetic data to assign paternity or parentage to individuals at the diploid level using microsatellite or SNP markers and the likelihood-based or Bayesian methods (Kalinowski et al., 2007; Jones and Wang, 2010; Anderson, 2012; Huisman, 2017), in addition to other approaches (Hayes, 2011; Heaton et al., 2014; Grashei et al., 2018; Whalen et al., 2019). For polyploids, the few resources available are limited to microsatellite data (Spielmann et al., 2015; Zwart et al., 2016). Another common approach in polyploids is to estimate pairwise relatedness (*r*) (Huang et al., 2015; Amadeu et al., 2020), for example, to assess the relationships between parents, offspring, full-sibs and half-sibs in progenies.

FIGURE 7 | Genotype analysis (GA)-based histograms of *Urochloa decumbens* with samples classified in the clustering analysis (CA). **(A–C)** show the results from GA-I, GA-II, and GA-III, respectively. The red circle highlights the identified apomictic clone (AC) contaminants in contrast to the hybrid progeny (HP).

In addition, identity-by-descent (IBD) has been used to assess the probabilities of inheritance of particular combinations of parental haplotypes (Zheng et al., 2016), which are also quite difficult to evaluate in polyploid progenies. For both approaches, the parameters are estimated in a pairwise manner, and the results are evaluated for each pair, making the analysis even more laborious.

For breeding programs that make use of biparental crosses, the major challenge is to precisely identify whether there are

contaminating individuals to be excluded from the progeny (Martuscello et al., 2009; Ma and Amos, 2012; Santos et al., 2014; Subashini et al., 2014; Simeão et al., 2016b; Matias et al., 2019; Deo et al., 2020). In this context, no studies have proposed a unified pipeline focused on identifying the most common contaminants in biparental crossings, especially in polyploid species, and supplying such a pipeline is the main objective of this work. Therefore, we propose an unprecedented semi-automatized pipeline that is based on principal component

analysis (PCA), genotypic analysis (GA), and clustering analysis (CA) to identify and classify all types of contaminants in a biparental progeny. The proposed methodology was developed and tested in F_1 biparental crosses of tropical forage grasses, but it can be applied to any tetraploid or hexaploid species since the parents of the F_1 biparental cross are known.

Contaminant Identification in Simulated Data Based on PCA, GA, and CA

Principal component analysis (PCA) is a multivariate data technique used to represent a dataset as orthogonal variables named principal components (PCs). Aiming at reducing the dimensionality of a set of variables through linear combinations, repeated information can be removed while the maximum variance-covariance structure of these variables is maintained (Jolliffe and Cadima, 2016). As the first two components explain the most variance in the SNP data, a scatter plot of the samples in a Cartesian plane with these PCs is a way to visually identify similarities and differences, and determine whether samples can be grouped (Ringnér, 2008). Our results showed that in a simulated biparental F_1 progeny without the presence of contaminants, the first components showed a two-dimensional pattern in which the population was distributed between the two parents (**Supplementary Figure 1**), which was expected since these individuals were closely related. As the first PCs generally reflect the variance related to the population structure in the sample, individuals from the same population form a unique cluster in a subspace spanned by the first two eigenvectors (Ma and Amos, 2012).

Considering the four simulated scenarios described above, a contaminant frequency of $\sim 3\%$ in a progeny is needed to observe a different pattern of PCs that allows the identification of contaminants (**Figure 2B** and **Supplementary Figures 5–7**), which shows the inefficiency of employing a PCA biplot for such an approach. In cases with a lower percentage of apomictic clones (ACs), self-fertilization progenies (SPs), or half-siblings (HSs), duplicating the genotype of one of the parents to generate artificial clones proved to be an alternative way to change the dispersion pattern of individuals, inducing the projection of contaminants as separated from the real hybrids (**Supplementary Figures 11, 12**). This occurred because the values for the linear combination increased for the PC1 vector, and the source of variation changed to be based on the presence of inserted clones. On the other hand, we found that full contaminants (FCs) could be detected with fewer contaminating individuals (1.5% contaminants in relation to the total population) due to the different genetic backgrounds in relation to the progeny. This high genetic variability modifies the first components and thereby facilitates the identification of FCs in the PCA.

In general, PCA has a better-defined pattern that allows for more inferences about population relationships, not at the individual level (Patterson et al., 2006). It has been widely performed using microsatellite and SNP markers for diploid and polyploid species to evaluate population structure (Larsen et al., 2018; Lara et al., 2019), to infer genetic ancestry (Byun

et al., 2017), to predict genomic breeding values (Macciotta et al., 2010), and for other applications. However, for contaminant identification, the use of the first components from PCA, even those successfully employed in forage grass polyploids (Lara et al., 2019; Deo et al., 2020), proved to be insufficient in most scenarios; therefore, other approaches are required.

In the pipeline described here, we propose the use of PCA to visualize the data and produce information that suggest the presence of possible contaminants in biparental crosses. The main limitation of PCA lies in cases with few contaminants, i.e., $<3\%$ of the progeny, which has already been reported in tropical forage grasses (Deo et al., 2020). Artificially inserting simulated clones from one of the parents changed the dispersion pattern in most cases; however, when the contaminants were HSs or FCs, the variance was still not captured by the first components. Therefore, PCA itself could not effectively identify and classify the contaminants and, for this reason, was combined with other techniques. We suggested the use of specific GA measures as inputs for CAs as a methodological workflow capable of identifying contaminants regardless of the type or quantity, overcoming the limitation of PCA in identifying contaminants in proportions below 3% of the total population.

The fundamental idea underlying GA-I, GA-II, and GA-III was to identify incompatibilities between putative hybrids and their parents as a strategy to conclusively demonstrate their parentage. For such analyses, it is expected that the GA scores from different populations (here, hybrids and contaminants) form different distributions with specific parameters. Although there are other approaches for parentage estimation already discussed in the literature, such as Identity by Descent (IBD) or pairwise relatedness (r) (Huang et al., 2015; Zheng et al., 2016; Amadeu et al., 2020), these measures indicate how close an individual is to another in a given population, regardless of the degree of relationship. GA measures, on the other hand, differ from these in terms of their focus on the genetic relationships in biparental populations for which both parents are known. Here, the main objective is to compute scores that are related to the type of contaminants expected in such populations, enabling not only identification but also classification.

In all simulated populations with 689 or more genotyped markers, the proposed methodology could correctly identify and classify almost 100% of the samples, ratifying the appropriateness of the proposed pipeline. The size of the markers set employed in different scenarios has been demonstrated to have a large effect on the accuracy of the methodology, as we observed a positive correlation between the two variables. Nevertheless, considering the most indicated clustering scheme, sets with more than 689 markers did not cause an expressive accuracy increase (**Figure 5**). Previous studies have evaluated accuracies in the function of number of markers in different genomic approaches, such as parentage assignment and genomic selection, and found similar results (Wang, 2012; Arruda et al., 2015; Lenz et al., 2017; Whalen et al., 2019). However, finding and generalizing the optimal number of markers for this methodology is complicated because it may be influenced by various factors, including the species, population size, contaminants quantity/type, and sequencing/genotyping techniques.

Even though the CA identifies different groups of individuals with similar GA measures, the association of each group with a contaminant type requires an additional step, which is important because identifying the type of contamination (in the case of AC or SP contamination) can assist the breeder to better understand the reproductive biology of the species or genotype. On the other hand, identifying HS or FC contaminants highlights the need for greater control during the field experiment, avoiding foreign pollen or seed mixtures. Interestingly, we noticed that each cluster captured a distinct pattern in the GA measures, a phenomenon that can be leveraged to decipher the contaminant origin of the individuals. Importantly, by using the proposed approach, we did not find any configuration in which true hybrids were discarded, which is of great value for real applications.

In summary, our proposal is a unique methodology that brings together all types of contamination in a single identification pipeline, representing an important resource for breeders, who need specific tools to deal with such contamination. Instead of relying solely on the putative population structure revealed by PCA methodologies, genotypic analysis (GA) indexes are calculated, taking into account the genetics behind the origin of the contaminants. Compared to the exclusive use of PCA, this pipeline identifies one or a few contaminating individuals with more confidence. This increased confidence makes this methodology ideal for situations in the field that lead to mixtures of seeds or foreign pollen during fertilization, which usually occurs at low rates.

Contamination Identification in Real Data

Principal component analysis, GA, and CA using genotypic data from the *Megathyrsus maximus*, *Urochloa decumbens*, and *Urochloa humidicola* F₁ progenies led to the conclusion that these real progenies had AC contaminants (Supplementary Figures 15, 17 and Figure 7). For *M. maximus*, the two detected clones (1.4% of the population) corroborated the findings of Deo et al. (2020), while for *U. decumbens*, 52 individuals (21.7% of the population) were identified as clones of the male parent. It is possible that these clones were inserted into these two progenies during seed collection. Additionally, the male parent was used as a control in the field experiments, and the plants may have produced seeds and/or seedlings that became mixed with the real progeny. As the female parent of these populations was entirely sexual, the absence of SPs suggests the predominance of allogamy in these plants and self-incompatibility as the main mechanism to guarantee this mode of reproduction.

We extended this methodology for the identification of contaminants in hexaploid species, represented in this study by *U. humidicola* ($2n = 6x = 36$). GA-I and GA-II were performed in the same way as for tetraploid species, but GA-III was adapted considering the segregation and possible combination of gametes in hexaploid species. For the progeny of *U. humidicola*, the combined PC and GA-I histogram analysis suggested the presence of 61 clones of the female parent (21.8% of the population). This result suggests that the genotype H031

(CIAT 26146) also reproduces through facultative apomixis, even though it has been widely cited in the literature as a unique obligate sexual genotype of *U. humidicola* (Jungmann et al., 2010; Vigna et al., 2016). It is known that the expression of apomixis in the same genotype may vary with the flowering season in other grasses (Rios et al., 2013). It might be that the mode of reproduction of H031 was evaluated at the end of flowering or under a specific environmental condition when the proportion of sexuality was greater than apomixis; therefore, this genotype might be a facultative apomict with high rates of sexuality (Karunaratne et al., 2020). In addition, the sexual genotypes of the *Urochloa* spp. can present a certain degree of self-incompatibility (SI) (Keller-Grein et al., 1996; Dusi et al., 2010), and Worthington et al. (2019) reported the detection of 12 individuals derived from accidental self-pollination of *U. humidicola* H031. Therefore, there is a need to enrich the current understanding of *U. humidicola* biology and reproduction mode, which are important for developing suitable breeding and selection methods (Barcaccia and Albertini, 2013).

All three forage progenies used in this work have already been used in the studies previously developed for the construction of genetic maps. Deo et al. (2020) identified and removed two contaminants in *M. maximus* progeny by PCA, which were also identified as contaminants by our methodology. However, for the progeny of *U. decumbens* (Ferreira et al., 2019) and *U. humidicola* (Vigna et al., 2016), only an analysis of the bands of the hybrids identified by genotyping with dozens of microsatellites or single sequence repeats (SSRs) and random amplified polymorphic DNA (RAPD) markers (Bitencourt et al., 2008), respectively, was performed, and no clones could be identified through this approach. Therefore, the absence of an adequate methodology and/or a sufficient number of markers for the prior identification of contaminants has resulted in genetic maps constructed with genetic information including some false hybrids, and consequently, these maps may contain bias that should be considered by researchers.

Our methodology proved to be useful in practical situations of breeding programs of tropical forage grasses, including the identification of different progenies from multiparent crosses, which may be extended to other polyploid crops. The identification of contaminants in the early stages of breeding cycles can greatly increase the efficiency of programs, preventing costs with false hybrids that might otherwise only be discarded in the later phases of selection. Conversely, it allows for the size of the useful population to increase, optimizing the breeding populations. Although the use of molecular markers is not yet a reality in many breeding programs, it is important to assess potential expenses brought by false hybrids, which might surpass the cost of large-scale genotyping technologies (such as GBS), which have been experiencing considerable cheapening in the recent years. PCA, GA, and CA were combined in a simple and semi-automated pipeline, and the coupling of a low-cost genotyping with such pipeline thus allows for a more precise and efficient detection of incompatibilities between a group of putative hybrids and the

identification of contaminants in biparental crosses of tetraploid and hexaploid species.

The implementation of this simple approach in the identification of contaminants in biparental progenies of polyploid species can increase the efficiency of breeding programs. In this context, the polyCID Shiny app was designed to enhance the ability of breeders to use our methodology, even with no bioinformatics expertise. Great advances in sequencing technologies and genotyping tools have enabled us to explore vast amounts of genetic data in a more cost-effective and faster way; however, the ability to handle and apply this genome information to breeding remains a significant barrier for most breeders and experimental researchers. Therefore, we designed the polyCID Shiny app as an interactive and user-friendly application that is completely R based and easy to install, incorporating the analysis in a single environment and enabling the users to extract information on contaminant individuals without requiring knowledge of a programming language.

Finally, although our analyses were performed with real and simulated progenies of tropical forage grasses, this methodology can be extended to any biparental progeny of tetraploid or hexaploid species. It can be applied in the early stages of genomic studies with GBS in biparental polyploid progenies, such as genetic linkage map construction and genomic prediction, to identify possible contaminants. However, as the price of SNP genotyping is constantly decreasing and other polyploid genotyping tools are emerging, the application of our methodology even in experiments that do not involve SNPs may be possible, mainly in the intermediate and final stages of the breeding program to confirm the absence of contamination in the final stages and cultivar release. In the case of genotyping with a lower number of molecular markers, it is suggested that simulation studies be carried out *a priori*, taking into account how the number and quality of the markers affect the final results.

1 Supplementary Methods

1.1 Genotype Analysis of simulated data

Supplementary Table 1: Expected and not expected genotypes based on all possible parental allele dosage for a tetraploid.

Progenitors (P1xP2)	Expected	Not expected
0 x 0	0	1, 2, 3, 4
0 x 1; 1 x 0	0, 1	2, 3, 4
0 x 2; 2 x 0	0, 1, 2	3, 4
0 x 3; 3 x 0	1, 2	0, 3, 4
0 x 4; 4 x 0	2	0, 1, 3, 4
1 x 1	0, 1, 2	3, 4
1 x 2; 2 x 1	0, 1, 2, 3	4
1 x 3; 3 x 1	1, 2, 3	0, 4
1 x 4; 4 x 1	2, 3	0, 1, 4
2 x 2	0, 1, 2, 3, 4	NA
2 x 3; 3 x 2	1, 2, 3, 4	0
2 x 4; 4 x 2	2, 3, 4	0, 1
3 x 3	2, 3, 4	0, 1
3 x 4; 4 x 3	3, 4	0, 1, 2
4 x 4	4	0, 1, 2, 3

1.2 Clustering Indexes

Supplementary Table 2. Overview of the indexes implemented in the NbClust package.

Name of the index in NbClust	Name of the index in the literature	References
"kl"	KL	(Krzanowski and Lai, 1988)
"ch"	Calinski and Harabasz	(Calinski and Harabasz, 1974)
"hartigan"	Hartigan	(Hartigan, 1975)
"ccc"	Cubic clustering criterion (CCC)	(Sarle, 1983)
"scott"	$n \log (T / W)$	(Scott, 1971)
"marriot"	$k^2 W $	(Marriot, 1971)
"trcovw"	Trace Cov W	(Milligan and Cooper, 1985)
"tracew"	Trace W	(Edwards and Cavalli-Sforza, 1965; Friedman and Rubin, 1967)
"friedman"	Trace $W^{-1}B$	(Friedman and Rubin, 1967)
"rubin"	$ T / W $	(Friedman and Rubin, 1967)
"cindex"	C-index	(Hubert and Levin, 1976)
"db"	Davies and Bouldin	(Davies and Bouldin, 1979)
"silhouette"	Silhouette	(Rousseeuw, 1987)
"duda"	$Je(2)/Je(1)$	(Duda and Hart, 1973)
"pseudot2"	Pseudot ²	(Duda and Hart, 1973)
"beale"	Beale	(Beale, 1969)
"ratkowsky"	c/k^5	(Ratkowsky and Lance, 1978)
"ball"	Ball and Hall	(Ball and Hall, 1965)
"ptbiseria"	Point-Biserial	(Kraemer, 1982)
"gap"	Gap	(Tibshirani et al., 2001)
"mcclain"	McClain and Rao	(Mcclain et al., 1975)
"gamma"	Gamma	(Baker and Hubert, 1975)
"gplus"	G(+)	(Rohlf, 1974)

"tau"	Tau	(Rohlf, 1974)
"dunn"	Dunn	(Dunn, 1974)
"sdindex"	SD	(Halkidi et al., 2000)
"sdbw"	SDbw	(Halkidi et al., 2001)

2 Supplementary Results

2.1 Simulation Details

The constructed linkage map used in PedigreeSim software consists of 8 chromosomes with 5,516 randomly distributed SNPs; the length, centromere position and number of markers of each chromosome can be found in Supplementary Table 1. Furthermore, as the software requires the parental genotypes for the markers to simulate the crosses, the *M. maximus* and *U. decumbens* parental allele dosage rates were used to genotype the simulated parents (P1, P2, P3 and P4), and the actual number of markers for each dosage in the set of 5,516 markers is shown in Supplementary Tables 2 and 3.

Supplementary Table 3. Information on the linkage map created for the simulation analysis.

Chromosome	Size (cM)	Position of the centromere (cM)	Number of markers
1	108	44	665
2	98	50	615
3	101	17	643
4	99	43	644
5	115	27	685
6	110	45	766
7	112	39	611
8	95	29	887

Supplementary Table 4. Rates of each allele dosage used to genotype the simulated parents. P1 and P2 were based on the parents of the *M. maximus* progeny, and P3 and P4 were based on the parents of the *U. decumbens* progeny.

	Nulliplex (0)	Simplex (1)	Duplex (2)	Triplex (3)	Quadruplex (4)
P1	0.4253	0.3899	0.1694	0.0110	0.0044
P2	0.3061	0.5255	0.1440	0.0213	0.0031
P3	0.5430	0.3008	0.1429	0.0098	0.0035
P4	0.1559	0.4930	0.2802	0.0671	0.0038

Supplementary Table 5. Number of SNP markers classified in each of the five possible dosage classes for the simulated parents, totaling 5,516 markers.

	Nulliplex (0)	Simplex (1)	Duplex (2)	Triplex (3)	Quadruplex (4)
P1	2,447	2,090	897	56	26
P2	1,652	2,876	833	138	17
P3	3,002	1,686	769	42	17
P4	848	2,705	1,552	388	23

2.2 Principal Component Analysis of Simulated Populations

Supplementary Figure 1. Principal component analysis scatter plot showing the simulated population with two parents (P1 and P2) and 200 hybrids (HP (P1xP2)). The axes represent the first and second principal components, which explain 2.1% and 1.9% of the variance, respectively.

Supplementary Figure 2. Principal component analysis scatter plot showing the simulated population with two parents (P1 and P2), 199 hybrids (HP P1xP2) and one self-fertilization progeny (SP (P1xP1)). The axes represent the first and second principal components, which explain 2.1% and 1.9% of the variance, respectively.

Supplementary Figure 3. Principal component analysis scatter plot showing the simulated population with two parents (P1 and P2), 199 hybrids (HP (P1 x P2)) and one half-sibling (HS (P1 x P3)). The axes represent the first and second principal components, which explain 2.1% and 1.9% of the variance, respectively.

Supplementary Figure 4. Principal component analysis scatter plot showing the simulated population with two parents (P1 and P2), 199 hybrids (HP (P1 x P2)) and one full contaminant (FC (P3 x P4)). The axes represent the first and second principal components, which explain 2.1% and 1.9% of the variance, respectively.

Supplementary Figure 5. Principal component analysis scatter plot showing the simulated population with two parents (P1 and P2), 196 hybrids (HP (P1 x P2)) and four self-fertilization progenies (SP (P1 x P1)). The axes represent the first and second principal components, which explain 2.2% and 2% of the variance, respectively.

Supplementary Figure 6. Principal component analysis scatter plot showing the simulated population with two parents (P1 and P2), 194 hybrids (HP (P1 x P2)) and six half-siblings (HS (P1 x P3)). The axes represent the first and second principal components, which explain 2.1% and 2% of the variance, respectively.

Supplementary Figure 7. Principal component analysis scatter plot showing the simulated population with two parents (P1 and P2), 197 hybrids (HP (P1 x P2)) and three full contaminants (FC (P3 x P4)). The axes represent the first and second principal components, which explain 2.1% and 1.9% of the variance, respectively.

Supplementary Figure 8. Principal component analysis scatter plot showing the simulated population with two parents (P1 and P2), 150 hybrids (HP (P1 x P2)) and 50 self-fertilization progenies (SP (P1 x P1)). The axes represent the first and second principal components, which explain 9.1% and 1.9% of the variance, respectively.

Supplementary Figure 9. Principal component analysis scatter plot showing the simulated population with two parents (P1 and P2), 150 hybrids (HP (P1 x P2)) and 50 half-siblings (HS (P1 x P3)). The axes represent the first and second principal components, which explain 9.1% and 1.7% of the variance, respectively.

Supplementary Figure 10. Principal component analysis scatter plot showing the simulated population with two parents (P1 and P2), 150 hybrids (HP (P1 x P2)) and 50 full contaminants (FC (P3 x P4)). The axes represent the first and second principal components, which explain 15.5% and 1.5% of the variance, respectively.

Supplementary Figure 11. Principal component analysis scatter plot showing the simulated population with two parents (P1 and P2), 199 hybrids (HP (P1 x P2)), one self-fertilization (SP (P1 x P1)) and 50 apomictic clones (AC (P1)). The axes represent the first and second principal components, which explain 8.6% and 1.8% of the variance, respectively.

Supplementary Figure 12. Principal component analysis scatter plot showing the simulated population with two parents (P1 and P2), 199 HPs (P1 x P2), one half-sibling (HS (P1 x P3)) and 50 apomictic clones (AC (P1)). The axes represent the first and second principal components, which explain 8.5% and 1.8% of the variance, respectively.

Supplementary Figure 13. Principal component analysis scatter plot showing the simulated population with two parents (P1 and P2), 199 HPs (P1 x P2), one full contaminant (FC (P3 x P4)) and 50 apomictic clones (AC (P1)). The axes represent the first and second principal components, which explain 8.4% and 1.8% of the variance, respectively.

2.3 Megathyrus maximus

Supplementary Figure 14. Principal component analysis (PCA) scatter plots showing the *M. maximus* progeny for the set of SNP markers filtered by a *prop_mis* value of 0.20. (A) Original population composed of two parents (P1 and P2) and their progeny of 136 hybrids (HP (P1xP2)); (B) Population with 36 simulated apomictic clones (S AC (P1)); (C) Population without the 2 apomictic clones (AC) identified. The axes represent the first and second principal components, which explain 3.8% and 3.8% of the variance for (A), 13.8% and 2.9% for (B), and 3.9% and 3.5% for (C), respectively.

Supplementary Figure 15. *Megathyrus maximus* GA histograms with samples classified by the two clusters obtained in the CA. (A), (B) and (C) show the results for GA-I, GA-II and GA-III, respectively. The red circle highlights the identified AC contaminants in contrast to the hybrid progeny (HP).

2.4 *Urochloa humidicola*

Supplementary Figure 16. Principal component analysis (PCA) scatter plots showing the *U. humidicola* progeny for the set of SNP markers filtered by a *prop_mis* value of 0.20. **(A)** Original population composed of two parents (P1 and P2) and their progeny of 276 hybrids (HP (P1xP2)); **(B)** Population without the 65 apomictic clones (AC) identified. The axes represent the first and second principal components, which explain 29.3% and 3.0% of the variance for **(A)** and 4.5% and 3.7% for **(B)**, respectively.

Supplementary Figure 17. *Urochloa humidicola* GA histograms with samples classified by the two clusters obtained in the CA. (A), (B) and (C) show the results for GA-I, GA-II and GA-III, respectively. The red circle highlights the identified AC contaminants in contrast to the hybrid progeny (HP).

Abstract

Tropical forage grasses, especially species of the genus *Urochloa*, play an important role in cattle production being the main food source for the animals in the tropical/subtropical regions. Most of the species are apomictic and tetraploid, this gives special importance to *U. ruziziensis*, a sexual diploid species that can be tetraploidized to be used in interspecific crosses with apomictic species. As a means to auxiliate breeding programs, this study investigates the applicability of genome wide family prediction (GWFP) in *U. ruziziensis* half-sibling families to predict growth and biomass production. Machine learning and feature selection algorithms were used to reduce the number of markers necessary for prediction to approximately 11 markers and to enhance the predictive ability to approximately 0.9 across the phenotypes. Beyond that, to investigate the regulation of the agronomic traits, the position of the markers with more importance for the prediction were considered as putative QTLs, and in a multi-omic approach, genes obtained in the species transcriptome were mapped linked to those markers. Furthermore, a gene co-expression network was modeled enabling not only the investigation of the mapped genes but their co-expressed genes too. The functional annotation showed that the mapped genes are mainly associated with auxin transport and biosynthesis of lignin, flavonol and folic acid, while the co-expressed genes are associated with DNA metabolism, stress response and circadian rhythm. The results provided a viable marker-assisted breeding approach for tropical forages and identified target regions for future molecular studies on these agronomic traits.

1 - Introduction

Pastures composed of tropical forage grasses, with emphasis on grasses of the *Urochloa* genus, are the main food source for animals in the tropical and subtropical world, standing out in the economic sector related to the beef/milk and seed markets (Jank et al., 2014). The genetic improvement of *Urochloa* species is recent, started about 40 years ago, and challenging due to different polyploid levels, high heterozygosity, and predominantly mode of reproduction by apomixis (Ferreira et al., 2021; Simeão et al., 2021; Worthington et al., 2021). Among the main goals of the breeding programs are the launch of cultivars tolerant to biotic stresses, adapted to future climate changes, increased productivity and with better nutritional value to improve animal performance (Pereira et al., 2018a; Simeão et al., 2021).

These goals can be achieved more quickly with the inclusion of genomic selection (GS) in breeding cycles, which uses statistical models to perform genomic predictions (GP)

of plant performance from genetic markers, mainly single nucleotide polymorphisms (SNPs) (Daetwyler et al., 2013). Although the estimation of GP models has already been shown as feasible in other important polyploid crops (de Bem Oliveira et al., 2020; Pincot et al., 2020; Ferrão et al., 2021; Haile et al., 2021; Juliana et al., 2022; Petrasch et al., 2022), such a methodology has only recently started to be tested in *Urochloa* spp. (Matias et al., 2019a; Aono et al., 2022), and efforts must be made to achieve high-quality panels of markers and large-scale phenotyping (Simeão et al., 2021). Fortunately, two *Urochloa* spp. genomes came available recently, both of *U. ruziziensis* ($2n=2x=18$) (Pessoa-Filho et al., 2019; Worthington et al., 2021), enabling the detection of large numbers of SNPs with potential to improve model accuracy in GP analyses on *Urochloa* spp.

Traditionally, GP models employ a dense dataset of molecular markers to calculate genomic estimated breeding values (GEBV) at the individual level (Meuwissen et al., 2001). However, for *U. ruziziensis* and some other forage species, such as alfalfa and ryegrass, it is a common practice to employ the family (full or half-sibs) as the basic unit for phenotyping and selection (Simeão et al., 2012; Simeão et al., 2016a; Simeão et al., 2016b; Biazzi et al., 2017; Cericola et al., 2018; Jia et al., 2018; Andrade et al., 2022), making the development of genome-wide family prediction (GWFP) approaches more advantageous. By considering family-pools as the unit of measurement, genotyping efforts are reduced and, together with combined individual phenotypic values, the costs of developing GP models are also reduced (Zou et al., 2016; Rios et al., 2021; Murad Leite Andrade et al., 2022). In addition, the application of GWFP can increase the predictive ability and, consequently, affect the rate of genetic gains for complex traits, as reported in loblolly pine and alfalfa (Rios et al., 2021; Andrade et al., 2022).

To achieve family-pool markers, sequencing approaches can be employed to generate a large number of SNP markers (Elshire et al., 2011; Poland et al., 2012). Genotyping-by-Sequencing (GBS) is a low-cost and high-throughput genotyping method that can be used to identify SNPs even when no reference genome is available, although a reasonable sequencing depth must be needed to avoid too many missing data points (Thakral et al., 2022). GBS has been applied in several family-pool genotyping studies (Bélanger et al., 2016; Cericola et al., 2018; Schneider et al., 2022) because it obtains allele counts from the sequencing reads (Byrne et al., 2013). This way, for family-pools GP and association studies, the allele counts can be directly used, without the necessity of estimating allelic dosages (Ashraf et al., 2014; Guo et al., 2018).

The incorporation of machine learning (ML) methods in GP has been controversial, with some studies showing advantages (Ma et al., 2018; Waldman et al., 2020; Aono et al., 2022), and others not (Montesinos-López et al., 2019; Zingaretti et al., 2020; Crossa et al., 2019). However, several studies have shown ML-based strategies to reduce marker density, including feature selection (FS) techniques to select polymorphisms associated with the phenotype, increasing the predictive power of GP methods (Li et al., 2018; Aono et al., 2020; Pimenta et al., 2021; Aono et al., 2022).

In contrast to predictions from GP models, association studies such as quantitative trait locus (QTL) mapping and genome-wide association studies (GWAS) attempt to find individual markers associated with larger amounts of genetic variation, in order to understand the genetic architecture of complex traits (Zhang et al., 2014). Although modeling different aspects, both approaches have complementary advantages, providing robust information to detect the potential candidate genes for agronomic important traits. Some methodologies originally used for GP were applied in GWAS to detect loci associated with the trait of interest (Goddard et al., 2016; Wang et al., 2020; Wolc et al., 2022). On the other hand, association studies have already shown to be useful to improve GP (Zhang et al., 2014; Bian et al., 2017; Jeong et al., 2020). However, it is yet to be better investigated how multiple sources of multi-omics data can provide information about the genes and biological processes associated with a group of selected markers that improved GP for a complex quantitative trait.

Once these polymorphisms are identified, other omics approaches can be used to ensure a better understanding of the biological relationships between genes related to complex traits (Scossa et al., 2021). Traditionally, data generated by multiple levels of biological information (genomics, transcriptomics, proteomics) were analyzed separately. However, in recent times, data integration followed by appropriate statistical analysis have become a tool with great potential in elucidating biological meaning of the studied traits in human (Yang et al., 2014), microorganisms (Borin et al., 2018; Rosolen et al., 2022), animals (Parker Gaddis et al., 2016; Mateescu et al., 2017), and plants (Francisco et al., 2021; Cardoso-Silva et al., 2022). Despite its economic importance and availability of some datasets, no study incorporating multi-omics has been carried out on *U. ruziziensis* nor any species of *Urochloa* spp.

Here, we developed a genome-wide family prediction (GWFP) approach for *U. ruziziensis* using different models and strategies, including ML and FS algorithms, and combined multi-omic approaches for a deeper investigation of genes and biological processes

involved in target traits for forage grass breeding programs. We hope that these results will provide insights about the genotype and phenotype associations, expression patterns and functional implications not only to *U. ruziziensis*, but to all tropical forage grasses.

2 - Materials and methods

The following sections describe an integrative methodology for analyzing phenotypic, genomic and transcriptomic data to investigate genes associated with agronomic traits in a breeding population of *Urochloa ruziziensis* ($2n = 4x = 36$) (Fig. 1).

Figure 1. The approach established in this research can be divided into three main parts: (i) phenotyping and genotyping the population (1); (ii) identifying phenotypically associated markers through genomic prediction (2 and 3); and (iii) investigating the genes physically linked to the markers in a co-expression network (4, 5 and 6).

2.1 - *Urochloa ruziziensis* phenotyping

The progenies used in this study were generated as part of the *Urochloa* breeding program of the Brazilian Agricultural Research Corporation (Embrapa) Beef Cattle (EBC), Campo Grande, Mato Grosso do Sul State, Brazil (20°27'S, 54°37'W, 530m), as described by Simeão et al. (2012, 2016a,b). Briefly, seven sexual autotetraploid accessions (R30, R38, R41, R44, R46, R47 and R50) were replicated 20 times to compose an open pollination randomized field organized in 26 lines and 12 columns spaced by 2 meters. In 2012, 20 seeds from 59 plants with viable seed production and flowering synchrony were collected and used to compose the breeding progenies, totalizing 1180 half-sibling individuals. The experiment was planted in a randomized block design with one plant per plot, spaced by 1,5m (Simeão et al., 2016a,b). From the 59 half-sibling progenies, 50 were chosen based on the criteria of selecting the progenies with more plants that succeeded in the field.

The phenotypic evaluation was performed considering nine clippings at 15 cm height, being six of them in the wet season (1-3,7-9) and three in the dry season (4-6) where the climatological water balance was accessed through the AWC (Available Water Capacity) metric (Supplementary Fig. S1) (Simeao et al, 2016a,b). In addition to the nine clippings, we have a total (T) evaluation for each phenotype in the period. The agronomic traits evaluated in all clippings were: green matter yield (GM) and dry matter yield (DM), both in grams per family, and regrowth (RG), with scores varying from 0 to 6 as described by Figueiredo et al. (2012). In addition, in two clippings and T, about 200g of leaves and stems from each plant were used to estimate leaf dry matter yield (LDM) and stem dry matter yield (SDM). Considering that clipping 1 is discarded for the analysis, in total, we evaluated 33 different traits (clippings 2-9 and T for GM, DM and RG, clippings 2,5 and T for SDM and LDM).

Phenotype measures of each trait were evaluated according to the following mixed-effect model, implemented in the Selegen-REML/BLUP software (Resende, 2016):

$$y = \mu + Zm + e ,$$

where y is the vector of the averaged phenotype by family, μ is the overall mean fitted as a fixed effect, Z is the incidence matrix of family effects, m is the vector of random family genetic effects and e is the vector of random error effects. The half-sib family narrow-sense heritability (h^2) was estimated based on:

$$h^2 = \frac{0.25Va}{0.25Va + \frac{\sigma}{r}},$$

in which Va is the additive variance, r is number of replications and:

$$\sigma = Ve + 0.75Va,$$

where Ve is the error variance.

For creating GP models, we employed a family-based approach, where the mean trait value was calculated for each family; and to be able to compare the modeling results, all phenotype clippings were scaled between 0 and 1 using the Min-Max Scaler method. In order to perform a data descriptive analysis, we used boxplots to access the distribution and outliers, computed Pearson's correlation among all phenotype clippings and performed a Principal Component Analysis (PCA) to access population structure. The descriptive analysis was done in R (R Core Team, 2021), and all PCA and plots in the work were done using the package `pcaMethods` (Stacklies et al., 2007) and the package `ggplot2` (Wickham & Chang, 2016), respectively.

2.2 - Genotyping

Genomic DNA of all individuals was extracted using the DNeasy Plant kit (QIAGEN), and pooled according to each family, totalizing 50 samples. Genotyping-by-sequencing (GBS) libraries were constructed following the method proposed by Poland et al. (2012) using a combination of a rarely cutting enzyme (EcoT22I) and a frequently cutting enzyme (MspI). Subsequently, libraries were sequenced as 150-bp single-end reads using the High Output v2 Kit (Illumina, San Diego, CA, USA) in a NextSeq 500 platform (Illumina, San Diego, CA, USA).

We performed the quality evaluation of GBS raw sequence reads using FastQC version 0.11.5 (Andrews, S. 2010) and SNP calling using the TASSEL-GBS pipeline (Glaubitz et al., 2014) modified for polyploids (Pereira et al., 2018b). The reads were aligned to the *U. ruziziensis* genome (Pessoa-Filho et al, 2019) using the BowTie 2.3.1 aligner (Langmead et al., 2009) and only reads aligned one time were kept. SNP markers were filtered using VCFtools v0.1.17 (Danecek et al., 2011) with the following criteria: a minimum sequencing depth of 20 reads, no more than 25% missing data per site, biallelic SNPs only, and removal of redundant (same genotypes in all samples) markers from the sets.

The allele frequency for each marker was estimated as the ratio between the number of reads for the alternative allele and the total number of reads. Missing data were replaced by the site mean of allele frequency. Furthermore, a principal component analysis (PCA) was performed in the complete genotype data to access population structure.

2.3 - Feature selection and genomic prediction

In order to create subsets of markers for each phenotype clipping, three FS techniques were applied to the SNP data using the Python 3 library scikit-learn with default parameters (Pedregosa et al., 2011): gradient tree boosting (FS-1) (Chen & Guestrin, 2016), extremely randomized trees (FS-2) (Geurts, Ernst & Wehenkel, 2008), and random forest (FS-3) (Breiman, 2001). Then, in order to perform the modeling, we created the Feature Intersection (FI) data sets by evaluating the intersection of the FS methods considering markers that were selected by at least two FS techniques (FI-1) and markers that were selected by all three FS techniques (FI-2), according to Aono et al. (2020) and Aono et al. (2022).

As GP strategies, we estimated different models considering six regression approaches across the 33 traits and the reduced (FI-1 and FI-2) and complete versions of the dataset. We used the following regression strategies for the creation of the models, two conventional genomic prediction models using 20,000 iterations with a thinning of 5 and 2,000 of burn-in: the semi-parametric reproducing kernel Hilbert space (RKHS) with a Gaussian kernel (GK) as the covariance function using the R package BGGE v0.6.5 (Granato et al., 2018); a Bayesian ridge regression (BRR) using the R package BGLR v1.0.9 (Perez & de los Campos, 2014)); and four ML algorithms using the Python 3 library scikit-learn v1.0.2 with default parameters (Pedregosa et al., 2011): support vector machine (SVM) (Cristianini & Shawe-Taylor, 2000), random forest (RF) (Breiman, 2001), adaptive boosting (AB) (Freund & Schapire, 1997), and multilayer perceptron (MLP) neural network (Popescu et al., 2009).

The evaluation of the previously described models for GP was performed using a k-fold (k=5) cross validation strategy, repeated 100 times and measuring two metrics: Predictive Ability (PA) as Pearson correlation coefficient and Mean Squared Error (MSE).

To compare the models, the phenotype clippings and the datasets, we used ANOVAs with multiple comparisons by Tukey's tests implemented in the agricolae R package (De Mendiburu & De Mendiburu, 2020). For PA we considered the best scenario the ones that in the Tukey's test had "a" or "a" combined with other letters, such, "ab" or "abc", which means the highest values. On the other hand, for MSE a scenario is better when its MSE value is

lower. So, we consider the best scenario as the ones with the higher letter, or combined with other letters (i.e., “f”, “ef” or “def”).

2.4 - Major Importance markers

Once the results showed the best data set of markers for each phenotype clipping, we used the Random Forest (Breiman, 2001) algorithm to model the data and obtain the impurity importance for each feature (markers). Also known as the Gini importance (GI), it is the normalized total reduction of the criterion brought by the feature, the sum of the features importance is equal to 1. To create a Major Importance set of markers, we selected the top 3 Gini importance (GI) markers in each phenotype clipping. If these three did not sum 0.5, the next ones were selected until the condition was satisfied. Furthermore, a Principal Component Analysis (PCA) was performed using the Major Importance markers dataset.

2.5 - Transcriptome assembly, quantification and annotation

A previous RNA-Seq data of 11 genotypes of *U. ruziziensis* was used to assess gene expression (Hanley et al., 2021; NCBI BioProject PRJNA513453). Raw data were quality-trimmed using Trimmomatic v0.39 (Bolger, Lohse & Usadel, 2014) with the following parameters: ILLUMINACLIP:IlluminaAdapters.fa:2:30:10, LEADING:3, TRAILING:3 SLIDINGWINDOW:4:20, MINLEN:75 and HEADCROP:12. Then, the good quality reads were *de novo* assembled by Trinity v2.5.1 (Grabherr et al., 2011) considering a minimum contig length (--min_contig_length) of 300 bases, and assembly integrity was evaluated using the Trinity.pl package utility.

SALMON 1.1.0 (Patro et al., 2017) was used to quantify the transcript expression, followed by the summarization of the counts at the gene level by tximport R package (Soneson et al., 2015). Only genes with more than one transcript per million (TPM) in at least three of the 11 samples were kept, generating the filtered assembly without low-level expression genes. The longest isoform for each gene was selected, and BUSCO v5.2.2 (Manni et al., 2021) was used to evaluate the annotation completeness against the Viridiplantae database. Finally, we aligned the filtered assembly to the UniProt database (Bateman et al., 2020) using Blastx and Blastn 2.10.0 (Altschul et al., 1990) with an e-value cutoff of 1e-10. Gene Ontology (GO) terms were retrieved using Trinotate software (Bryant et al., 2017), which performed the functional annotation.

2.6 - Genes linked with markers and GO enrichment

To identify genes physically linked to major importance markers (section 2.9), we aligned the genes obtained from the transcriptome assembly (section 2.10) against the *U. ruziziensis* genome (Pessoa-Filho et al., 2019). So, genes that aligned in a window of 5,000 bp up and downstream the marker position were noted as physically linked. The alignment was performed using Blastn 2.10.0 (Altschul et al., 1990) considering a coverage of 0.75 and e-value of 1e-6, and the linked genes were identified using R (R Core Team, 2021). To visualize the genes position in the genome, a physical map was constructed using MapChart v2.32 (Voorrips, 2002) with information of phenotype and season association, and Gini importance. In addition, a circular map was constructed using the R package circlize v0.4.14 (Gu et al., 2014) to show the associated genes that were duplicated.

Finally, in order to obtain a functional profile of the genes linked to the markers, a biological process GO terms enrichment was performed considering only terms common to *Arabidopsis thaliana*. This step was achieved with R package topGO (Alexa & Rahnenfuhrer, 2022), and GO terms with p-value < 0.01 were considered significantly enriched.

2.7 - Co-expression network

We modeled a gene co-expression network (GCN) using the transcript quantifications normalized in transcript per million (TPM) and the highest reciprocal rank (HRR) (Mutwil et al., 2010) approach, considering a limit of 30 edges. From the GCN, we selected the genes associated with the agronomic traits; also including highly correlated genes which were not considered in the network ranking (Pearson correlation coefficient ≥ 0.9 and a maximum p-value of 0.01 with Bonferroni correction). From this set established, we selected the first and second gene neighbors in the GCN.

The network visualization and evaluation were performed using the Cytoscape software v3.9.1 (Shannon et al., 2003). For each gene, we calculated the degree centrality measure as Barabási & Oltvai, 2004. Lastly, biological process GO term enrichments were performed for the selected genes, including first and second neighbors, to produce a general and seasonal functional profile of the metabolic pathways associated to the agronomics traits, same method of 2.6.

3 - Results

3.1 - Phenotypic and Genotypic Data Analyses

In our study, we evaluated five important phenotypes for forage grasses (GM, DM, RG, LMD, and STM) in different clippings, selected based on wet and dry seasons. Individual measures were averaged at subfamily level. The descriptive analysis of subfamily-based phenotypic data did not reveal any apparent patterns concerning the dispersion and skewness of the traits (Supplementary Fig. S2). No outliers were detected in 17 of the 33 traits. Even without any evident dispersion similarity between the phenotypes evaluated, the correlation analysis showed significant values for all the comparisons performed (Supplementary Fig. S3). We observed an average R Pearson correlation coefficient of 0.72 (Supplementary Fig. S3), with the highest correlations (~ 1) between the same clippings of GM and DM. Furthermore, early clippings (2 and 3) tended to be less correlated to all other measures. This scenario was more evident in GM, DM and SDM. In contrast, SDM-2 was the trait less correlated with the other phenotypes (Supplementary Fig. S3). The progeny means narrow-sense heritabilities for all phenotype clippings showed a mean value of 0.79, ranging from 0.44 (SDM-2) to 0.92 (LDM-5) (Supplementary Table S1).

GBS experiments generated ~ 720 million reads, which were converted into 1.3 million tags using the Tassel pipeline. A total of 77,413 SNP markers were identified in this step, of which 28,106 were retained after quality filters, allele frequency estimation, and missing genotype imputation. This final dataset of markers was denominated complete data (CD).

By using the phenotypic and genotypic data, we performed PCAs, plotting the dispersion of subfamilies using the scores of the two first principal components (PCs) (Supplementary Figs. S4-S5). Although arising from different sources of variation (the proportion of variance explained by the first two PCs was 85.2% and 57.2% for the phenotypic and genotypic data, respectively), similar patterns could be observed. For corroborating such a similarity, we colored the samples from the genotypic PCA scatter plot using the PC1 of the phenotypic data. Even without a pronounced presence of 3 groups, as the phenotypic PCA, the coloring in the genotypic PCA evidenced a clear association between both PCA results (Supplementary Fig. S5).

3.2 - Family Based Genomic Prediction

The predictive performances for the 33 traits at family level using the CD were evaluated by considering two conventional genomic prediction models (RKHS and BRR). Applying a 100 times 5-fold CV strategy, the RKHS model showed slight superior results in respect to BRR, with a mean PA of ~ 0.762 and mean MSE of ~ 0.025 , contrasted to a mean PA of ~ 0.745 and a mean MSE of 0.026 in BRR. We observed a maximum PA of ~ 0.875 in the trait DM-8, and a minimum PA of ~ 0.490 in SDM-2. Aiming to obtain higher performances, four ML algorithms (SVM, RF, AB and MLP) were evaluated. Among the ML models, SVM had the best overall performance (PA mean of ~ 0.759 and MSE mean of ~ 0.026), however not superior to the RKHS approach. By considering the Tuckey's test results for MSE, SVM was highly overcome by the RKHS model, being considered the best approach in 13 traits while RKHS was considered in 30 (Supplementary Table S2-4). Our results indicate that when using CD for prediction, the ML algorithms were not able to outperform the conventional models.

In order to increase our predictive accuracies and evaluate putative trait-marker associations, specific subsets of SNPs were selected for each one of the 33 traits based on the intersections established between FS sets. Each one of the FS approaches generated a different quantity of markers: FS-1 selected sets with quantities ranging from 129 to 175 markers (mean of ~ 150 , 0.53% of the CD); FS-2 from 484 to 1154 (mean of ~ 848 , 3% of the CD); and FS-3 from 563 to 853 (mean of ~ 699 , 2.5% of the CD). By considering the intersection approaches selected, we obtained FI-1 with SNP quantities ranging from 76 to 122 markers (mean of ~ 102 , 0.36% of the CD) and FI-2 with quantities varying from 5 to 23 markers (mean ~ 11 , 0.04% of the CD) (Supplementary Table S5). In addition to obtaining more restricted sets, these markers selected by FI have more evidence of trait associations, as they were selected by more than one algorithm. In this sense, model performances using the CD were contrasted with the use of models created from the data sets selected by FI-1 and FI-2.

The employment of the FI datasets increased the performance of all models for all traits. This increase was prominent in the models AB and RF, which presented the highest accuracies observed, overcoming RKHS in both FI sets. In respect to the six models evaluated, the FI-1 approach presented an improved overall performance when compared to FI-2, being considered by the Tuckey's test the best approach in 168 (FI-2 = 100) and 136 (FI-2 = 89) scenarios for PA and MSE respectively (Supplementary Table S6). However, individual results for the best models in each scenario were similar, as indicated by the best

model in FI-1 (AB with a mean PA of ~ 0.894 and a mean MSE of ~ 0.013) and FI-2 (RF with a mean PA of ~ 0.893 and a mean MSE of ~ 0.013) (Supplementary Table S2-4). Furthermore, when analyzing the clippings of a phenotype, we saw that the best performances for clippings in AB-FI-1 and RF-FI-2 varied in GM and DM, but for RG (clipping 3), SDM (clipping 5) and LDM (clipping 5) the results were equivalent (Supplementary Table S2-3 and 7).

In this sense, we observed that, for the prediction task, the combinations AB-FI-1 and RF-FI-2 can be employed with similar performances. However, for investigating trait-marker associations and catalog putative associated genes, the FI-2 represents a more restrictive approach. With sets (mean of ~ 11 markers) approximately ten times smaller than the sets of FI-1 (mean of ~ 102 markers), FI-2 markers provide a group of markers with a probable decreased number of false positive associations. Therefore, we considered the combination RF-FI-2 as the most promising approach to be employed in our datasets. In addition to a significant decrease in marker density through FI-2, the RF algorithm demonstrated high efficiency for prediction with an increase of 5.9% when compared to the RKHS PA using the FI-2 dataset or 17% when compared to the RKHS using the CD dataset. (Table 1).

Table 1. Comparison of RKHS and RF models predictive ability and mean squared error for all phenotype clippings using the FI-2 data sets.

Phenotype Dataset			Green Mater				Dry Mater				Leaf Dry Mater				Stem Dry Mater				Regrowth			
			RKHS	RF	Diff	%	RKHS	RF	Diff	%	RKHS	RF	Diff	%	RKHS	RF	Diff	%	RKHS	RF	Diff	%

3.3 - Major Importance markers

Considering that the FS strategies employed in our study were based on ML algorithms estimated through a combination of decision trees, and also that the best model performances observed for FI-1 and FI-2 were AB and RF, respectively, we performed an additional approach to evaluate marker-trait associations based on decision tree structures: ranking the markers according to the RF scores estimated using the FI-2 selected markers. We selected the top three Gini importance markers for each trait, and if the top three did not present an importance sum of at least 0.5 (from a total of 1.0), we selected the next in the ranking until we achieved half of the total importance. In this way, we listed the markers with

the highest feature importances and avoided importance underrepresentation in traits. From all the FI-selected markers (283 markers) across the 33 traits, we could highlight a set of 69 markers with major prediction relevances, where only for SDM clipping 5 it was necessary to select four markers instead of three (Supplementary Table S8).

Furthermore, we performed a PCA to evaluate the subfamilies' dispersion considering this set of 69 major importance markers. The first two PCs explained 67.5% of the data variance, an intermediate value between the complete set of SNPs (57.2%) and the phenotypic data (85.2%) (Supplementary Fig. S6). Although the values of the first PCs seem to be inverted in such a PCA when compared to other ones performed, we observed a similar dispersion pattern (Supplementary Figs. S4 and S5). As we expected, the scatter plot displayed a group formation visually closer to the phenotypic PCA. Since the markers were selected through associations with the traits, there was a strong relation between the major importance data PC1 and the samples colored using the phenotypic PC1 values (Supplementary Fig. S7).

For evaluating the physical distribution of the FS selected markers, we created a *U. ruziziensis* physical map using the values obtained in the species genome. In addition to the set of 69 major importance selected markers, we also included in the map constructed all the FI-2 markers (Fig. 2). In regard to the markers distribution, we identified associations in all chromosomes with no clear pattern, except that there were extensive regions with little or no markers in the central region of chromosomes 1, 2, 5, 7 and 8, which we speculate as centromeric regions (Fig. 2). Chromosome 1 had more associations considering both FI and major importance sets, with little variation in representativeness, but it was the one with more SNPs identified too (Table 2). The smallest presence of associations was in Chromosomes 5 and 6 and the highest change in representativeness was in Chromosome 4 which had a reduction of 7% from FI to Major Importance (Table 2). Beyond that, especially in Chromosomes 1, 4 and 7, we observed regions with high density of minor importance markers around major importance markers, which may indicate that those are QTLs regions associated with the agronomic traits.

The Major Importance set was composed of various markers associated with more than one trait. As evidenced in the physical map, the marker associated with more traits clippings is in Chromosome 7, position 42,826,434. This marker was associated with four of the five phenotypes evaluated and was selected for nine clippings, of which in three it had Gini importance higher than 0.4 and in six GI between 0.2 and 0.4 (Fig. 2). Other markers were associated with various traits clippings, as a marker in Chromosome 1 position

69,834,400, that was associated with six traits clippings, and other three markers with four associations in Chromosome 1 and 3 (Fig. 2).

When considering the markers for each of the five traits without separating them by clippings, we accessed the sets intersections to quantify markers associated with more than one trait (Supplementary Fig. S7). Despite the difference in quantity between FI-2 and Major Importance sets, the logic relation among the traits sets was maintained: GM, DM and LDM were the phenotypes that shared more markers, while RG and SDM had proportionally more exclusive markers. Interestingly, SDM and RG were the traits with generally less correlation to the other traits too.

Table 2. Number and percentage of SNP markers identified/selected in each chromosome considering the Complete Data (CD), Feature Intersection (FI-2) and Top Gini Importance datasets.

Chromosome	Complete Data	Feature Intersection - 2	Top Gini Importance
1	4722 (16.8 %)	69 (23.4 %)	16 (23.2 %)
2	3565 (12.7 %)	36 (12.2 %)	10 (14.5 %)
3	3249 (11.6 %)	28 (9.5 %)	9 (13 %)
4	3552 (12.6 %)	42 (14.2 %)	5 (7.2 %)
5	1384 (4.9 %)	15 (5.1 %)	4 (5.8 %)
6	2508 (8.9 %)	23 (7.8 %)	2 (2.9 %)
7	3796 (13.5 %)	37 (12.5 %)	8 (11.6 %)
8	2127 (7.6 %)	18 (6.1 %)	8 (11.6 %)
9	2426 (8.6 %)	22 (7.5 %)	5 (7.2 %)
Scaffolds	777 (2.8 %)	5 (1,7 %)	2 (2.9 %)
Total	28106 (100 %)	295 (100 %)	69 (100%)

Figure 2. Physical map with the markers and genes associated with the phenotypes evaluated in the *Urochloa ruziziensis* population, with Gini Importance (GI) and Season indicated. Duplicated genes and minor importance markers (FI-2) mapped are represented in red and purple, respectively.

3.4 - Markers-genes associated with phenotypes.

To obtain insights into the agronomic traits regulation, we proceed to the identification of genes associated with the major importance markers. From the alignment of transcripts (Supplementary Results 2.1) with the reference genome of *U. ruziziensis* and, considering a window of 5,000 bp up/down stream the markers positions, we mapped a total of 217 genes (264 considering genes with multiple copies) physically close to 58 markers (Fig. 2 and Supplementary Table S8). We did not detect genes linked to all markers, as in Chromosome 1, where there were no genes in a marker region associated with six traits clippings, and in Chromosome 5, which from the four major importance markers, two had no linked genes (Fig. 2).

As previously stated, we found genes with multiple copies linked to more than one major importance marker region. There were 22 genes in this condition, which are highlighted in red in Fig. 2. For a better investigation of those genes, we mapped them in a circular map showing how the copies are positioned in the genome and united the copies information about trait/season associations and gini importance (Fig. 3). We identified five genes with six copies, three and two of them always appear together, and simultaneously, they are associated with seven traits clippings. Furthermore, we identified genes with 4, 3 and 2 copies associated to all evaluated traits and with different importances, demonstrating no clear pattern.

Regarding the functional annotation of the genes associated to the phenotypes, which is a subset of the complete transcriptome annotation obtained through the Trinotate and the UniProt database (Supplementary Results 2.1), we identified proteins/enzymes and GO terms for 100 of the 217 genes (Supplementary Table S8). Some interesting proteins were identified, as in the region associated with more traits, in Chromosome 7 (position 42,826,434). It had seven mapped genes, some were annotated as Cinnamoyl-CoA reductase 1 which participates in the lignin biosynthesis and DEAD-box ATP-dependent RNA helicase 25 which acts in response to abiotic stress. Furthermore, in Chromosome 1 (position 11,178,365), associated to four traits, there are genes annotated to the protein multidomain RHM2/MUM4, involved in UDP-D-glucose to UDP-L-rhamnose conversion which is required for the biosynthesis of cell wall (Supplementary Table S8).

Beyond specific protein annotation, to obtain a general functional profile of the proteins identified, we performed the enrichment of the biological process GO terms and obtained a profile with 18 significant terms ($p\text{-value} < 0.01$). The enrichment identified terms

associated with various phenotype clippings, such as “lignin biosynthetic process” , “auxin efflux” and “flavonol biosynthetic process” (Supplementary Table S10).

Figure 3. Circular map of the *U. ruziziensis* genome, indicating multiple copy genes identified as associated with the phenotypes evaluated, indicating Gini importance and Season. Same genes indicated with the same color, except genes with two copies.

3.5 - Co-expression network

In order to provide deeper insights into functional patterns of genes associated with the agronomic traits evaluated, we modeled a gene GCN using gene quantifications from *U. ruziziensis* accessions. From a total of 49,445 genes, we could estimate significant interactions between 14,141, represented as nodes in the network structure and associated through 17,812 edges (Supplementary Fig. S8). In the GCN, we found 54 genes from the 217 genes associated with the major importance markers. As we restricted the GCN created to the top 30 gene associations, we expanded the collection of 54 selected genes to more 109 by

considering correlations with a minimum Pearson coefficient of 0.9 and a Bonferroni corrected p-value of 0.01. This group of 153 genes was considered directly associated with the traits evaluated.

The GCN potential to elucidate the metabolic pathways lies in the possibility to identify genes that, even though were not selected by the prediction methodology, are co-expressed with them. In this sense, we expanded the set of 153 genes previously selected, to the GCN first (308 genes) and second gene neighbors (2233 genes), to compose an agronomic traits network with a total of 2704 genes (nodes) and 3453 edges (Fig 4-A).

The functional profile of the agronomic traits network, obtained through the enrichment of the biological process GO terms, identified 11 significant terms ($p < 0.01$) for the genes set without the second neighbors and 16 terms considering all genes in the network (Supplementary Table S11). When we consider the restricted set without the second neighbors, we found enriched terms related to hormones as auxin efflux and abscisic acid transport; and biosynthetic processes of molecules such as the flavonoids. In the broader set, including second neighbors, we found terms related to DNA metabolism as: mismatch repair, DNA replication and DNA duplex unwinding. Other terms enriched were for biotic stress: response to chitin; and regulation of circadian rhythm.

Another interesting aspect of the GCN to investigate regulation of metabolic pathways, is that by identifying the genes with more connections in the network through the degree metric, we can find important genes that regulate the functioning of many others. Consequently, those genes with high degree values may have an important role in the expression of the phenotypes that we are studying. In our modeled agronomic traits network, we found some interesting genes with many connections, like the ones that translate into the ribosomal proteins 40S S6 and 60S L9, protein ELF4-LIKE 4 or 14-3-3 protein zeta (Supplementary Table S12).

Furthermore, to investigate the differences in respect to wet and dry seasons, we separated the genes of the general network related to each season and evidenced them in the network. The wet and dry parts of the network comprises 33 and 22 genes associated with the major importance markers, 58 and 54 highly correlated, 102 and 231 first neighbors, 1322 and 1359 second neighbors, and totalized 1515 and 1666 genes (nodes) with 1801 and 2205 edges, respectively (Fig 4-B,C). Comparing the seasons functional profile, we found shared terms as: flavonol biosynthetic process, auxin efflux and mitotic recombination-dependent replication fork processing. And season specific terms, like abscisic acid transport, isoleucine biosynthetic process, response to nematode and chaperone-mediated protein

folding for wet season. And for dry season, we found enriched terms as: pyridoxal phosphate biosynthetic process, response to water deprivation and response to chitin, which are terms related to stress response (Supplementary Table S13 and S14).

Figure 4. Selected and correlated genes co-expression network with first and second neighbors. A) Major importance genes in blue, highly correlated genes in yellow, first neighbors in green and second neighbors in gray. B) Genes associated with the wet season trait clippings. C) Genes associated with the dry season trait clippings.

4 - Discussion

Tropical forage grasses play an important role in the global economy and in the supply of milk and meat. Thus, the increase in productivity and quality of these species, mainly from the *Urochloa* genus, can result in more sustainable livestock production and positively impact food and nutrition security. Although conventional breeding of tropical forage grasses has resulted in the release of superior cultivars in recent decades, the genetic gains are low and molecular breeding still not being used due to the genus scarce genomic resources and genomic complexity (Simeão et al., 2021, Ferreira et al., 2021). Besides the difficulties, the recent advances in omics approaches and computational methods for polyploid species has enabled the emergence of studies in *Urochloa* breeding important areas, such as genome assembly (Pessoa-Filho et al., 2018; Worthington et al., 2021), contaminant identification (Martins et al., 2021), transcriptomics (Vigna et al., 2016a, Worthington et al., 2021, Jones et al., 2021; Hanley et al., 2021), linkage and QTL mapping (Vigna et al., 2016b; Thaikua et al., 2016; Ferreira et al., 2016; Worthington et al., 2021), GWAS (Matias et al., 2019b) and genomic selection/prediction (Matias et al., 2019a, Aono et al., 2022). By integrating the few genetic resources available through bioinformatics and not explored techniques, such as machine learning feature selection and complex networks, we developed

a multi-omic approach capable of expanding the molecular breeding knowledge that can be used in the *Urochloa* genus.

Following this sense, we conducted our study considering 49 *Urochloa ruziziensis* subfamilies genotyped with 28,106 high quality markers and phenotyped in 33 characteristics, which are clippings for the agronomic phenotypes GM, DM, SDM, LDM and RG. In our first approach for genome wide family prediction (GWFP), we employed the complete markers dataset (CD) with conventional parametric and semiparametric GP models (BRR and RKHS) and obtained higher or at least equivalent PA in comparison to other GWFP studies. Even though not with *Urochloa* species, there are studies with forages that evaluated the prediction of dry matter. While we had a high mean PA of ~0.8 for the DM clippings, in alfalfa it had values smaller than 0.7 (Murad Leite Andrade et al., 2022) and in ryegrass it had a low PA of 0.34 (Guo et al., 2018). If we consider the GWFP of other phenotypes, like rust resistance and heading date in alfalfa (Murad Leite Andrade et al., 2022) or ligning , stiffness and diameter in loblolly pine (Rios et al., 2021), they were still smaller than our results, which had a mean PA across the 33 traits of ~0.762. The performance that we obtained seems even more promising when we compare to genomic prediction performed at individual level in tropical forages. The studies with *U. ruziziensis* interspecific hybrids (Matias et al., 2019a), *U. decumbens* (Aono et al., 2022) *M. maximum* (de C. Lara et al., 2019; Aono et al., 2022) and with *P. virgatum* (Lipka et al., 2014), obtained PA ranging from values close to zero to maximum values of 0.7 when evaluating several agronomic and morphological traits. The highest values were obtained for *U. decumbens* and *M. maximum* in agronomic traits after feature selection strategies with integration of ML methods that increased the PAs (Aono et al., 2022).

The application of ML algorithms in genomic prediction has been investigated in a variety of species and phenotypes (Grinberg et al., 2016; Lello et al., 2018; Zhao et al., 2020; Liang et al., 2020; Chung et al., 2021; Islam et al., 2021; Sandhu et al., 2021), and besides that there is no empirical evidence in support of the supremacy of ML methods over linear methods (Zingaretti et al., 2020; Varshney, 2021), it has performed better or at least equal to conventional models in various situations (Bellot et al., 2018; Abdollahi-Arpanahi et al., 2020; Liang et al., 2021; Wang et al. 2022). It is discussed that the ML methods finds its potential to outperform conventional models especially when dealing with complex phenotypes controlled by high dominance and epistatic effects (Wang et al., 2018; Tong & Nikoloski, 2021), and beyond that, there are no studies investigating its applicability in GWFP. This way, in addition to the parametric (BRR) and semiparametric (RKHS) models,

we evaluated four ML models (SVM, RF, AB and MLP) and none was able to outperform the RKHS model. Although SVM had competitive performances for PA, it was not as good for MSE; RF and AB had intermediate performances and MLP was the worst by far (Supplementary Tables S2-4). The bad performance of MLP may be related to the small sample size of our data set, since neural networks methods commonly require large data sets for good predictions (Bellot et al., 2018; Montesinos-López et al., 2021).

Although ML algorithms have been showing similar performances to the conventional models for genomic prediction, some of them offers methods to feature selection (FS), which is a common strategy in data science to remove redundant, incorrect or irrelevant data from the dataset and in some cases enhance the modeling performance (Miao & Niu, 2016; Cai et al., 2018). FS has been applied in genomic prediction and produced interesting results, enabling enhanced prediction or at least equivalent performances with smaller markers datasets (Li et al. 2018; Azodi et al., 2019 (A); Luo et al., 2021; Piles et al., 2021). On this wise, we applied three FS methods based on decision tree algorithms (gradient tree boosting, extremely randomized trees and random forest) in our markers dataset and following the intersection approach, we created two intersection (FI) datasets (FI-1: intersection of at least two FS; FI-2: intersection among all FS) for each of the 33 traits. This approach of using FI to compose smaller data sets with putatively more reliable markers for prediction, has been applied in grasses and produced improved results (Aono et al., 2020; Pimenta et al., 2021; Aono et al., 2022; Pimenta et al., 2022). For the traits evaluated in this study, the FI-1 and FI-2 dataset types had a mean size of ~102 and ~11 markers, respectively, and both produced improved prediction results in all models. Even though FI-1 had better performance across models, the best model for each FI (FI-1:AB; FI-2:RF) were equivalent, and represented a mean PA increase of 5.9% in comparison to the RKHS with CD (Table 1).

In regard to the analyzed agronomic traits, we observed a high correlation among evaluations and it was expected since the biomass characteristics evaluated are very similar and may be controlled mainly by the same metabolic processes. DM phenotyping is done by drying the GM material, and SDM/LDM by separating the DM into stem and leaf, furthermore, the biomass production depends on the plant growth capacity (RG). For that reason, the families narrow sense heritabilities for the traits were very similar too, and as stated in other studies, modeling performances are strongly influenced by heritabilities (Wang et al., 2018; Xu et al., 2018; Murad Leite Andrade et al., 2022), consequently, our prediction performances did not vary much and were correlated to the heritabilities (Supplementary Table S1, 2 and 3). Interestingly, the use of FS/FI had more impact increasing the PAs of the

clippings with less heritabilities (GM-2/3, DM-2/3, SDM-2, RG-8/9), making the prediction performances across the 33 traits less variable in comparison to CD.

We believe that such high PA in our predictions may be related mainly to the small population size and the low genetic diversity among samples. The diversity is low because the population was obtained from a open pollination cross of only seven sexual genotypes and as seen in the CD PCA scatterplot (Supplementary Fig. S5), the diversity is defined by the formation of 3 groups where most samples are concentrated in one group. This combination is reported to produce high predictive abilities as observed in wheat (Edwards et al., 2019). Furthermore, there are works demonstrating that increasing the population with genetically distant samples makes the prediction task more difficult and consequently reduces its accuracy (Lorenz & Smith, 2015; Berro et al., 2019).

Beyond the well known advantages of genomic selection related to the power to shorten the time of breeding process (Simeão-Resende et al., 2014) and to reduce the phenotyping costs (Crossa et al., 2017). The use of GWFP has other advantages, specially in forage breeding programs, which commonly uses families or plot level phenotyping for conventional breeding (Rios et al., 2021). Besides its apparent higher performance over individual level GP, when performed using ML models coupled with FS/FI strategies, it has the potential to strongly reduce the costs of genotyping. First because large populations can be reduced to family samples and second, because despite the necessity of genotyping the training population with a high number of markers in order to perform FS/FI, the samples that are going to be predicted can be genotyped only for the small FI set.

In addition, for its application in breeding programs or further studies, we would recommend experimental designs prioritizing more families instead of more individuals per family. Even though not with half-sibling families, there are works with tetraploid full siblings families that concluded that six individuals would be enough to represent the family variation both in genotyping and phenotyping (de Bem Oliveira et al. 2020; Rios et al., 2021), evidencing that bulking 20 individuals per family as we did may be unnecessary. Furthermore, to a certain extent, increasing the training population has the potential to improve the GWFP performance (Fé et al. 2015).

Beyond the applicability analysis of GWFP in *U. ruziziensis*, the present work aimed to investigate the agronomic traits metabolic regulation, and as a first step to achieve this objective, we identified marker-phenotype associations. To this extent, the high PA and the performance enhancing using FS/FI evidences that the selected sets of markers are putatively associated with QTLs, and can be used to study molecular processes involved in the trait

predicted (Steinfath et al., 2010; Heer et al., 2018; Zhou et al., 2019; Aono et al., 2020; Pimenta et al., 2021; Aono et al., 2022; Pimenta et al., 2022). In parallel to other approaches to identify genotype-phenotype associations, the FS techniques does not depend on specific bi-parental populations (RILs, NILs, F2, etc) as is necessary for QTL mapping (Mohan et al., 1997; Dhingani et al., 2015) and can identify non-linear and complex associations which is a limitation of linear models used in GWAS (Korte & Farlo, 2013).

Furthermore, the ML models based on decision trees offer a good prediction interpretability since it is possible to assess feature importance through Gini importance, and in the context of genomic prediction, it can rank markers based on the strength of the association with the modeled phenotype (Azodi et al., 2019b; Bayer et al., 2021; Medina et al., 2021). This way, considering that the best model for each FI dataset type was equivalent, we computed the RF Gini importance for the more restricted FI-2 datasets and selected the most significant features to compose an even smaller and more reliable set of agronomic traits associated markers (Supplementary Table S8). In this major importance set, we identified markers associated with more than one phenotype, the number of shared markers was representative only for GM, DM and LDM, which may indicate the similarity of the biological processes behind the phenotypes, while SDM and RG seems to be controlled by specific/exclusive metabolic pathways, which is corroborated by the smaller correlation of SDM and RG with the other phenotypes (Supplementary Fig S3 and S6).

By using half-sibling families bulks as a representation of the genetic variability available for breeding, genotyping similar agronomic traits in various clippings and selecting only the most influential markers in the predictions, we were able to minimize the limitations of the method due to small sample size and obtain a reliable set of markers to use as a guide to identify genes/regions involved in the regulation of the species' agronomic traits. In the absence of genome annotation, we employed a multi-omic approach integrating RNA-seq data in the analysis to identify and annotate expressed genes physically linked to the selected markers (Supplementary Table S8).

The enrichment of the terms related to the annotated genes evidences the methodology capacity of in fact identifying QTL regions influencing the evaluated agronomic traits (Supplementary Table S10). Associated with various phenotype clippings, we had terms related to lignin biosynthetic process, which has been previously reported to have strong influence in plant development (Yoon, Choi & An, 2015; Bahri et al., 2020), where mutants of lignin biosynthesis genes showed phenotypes of dwarfism/reduced plant growth (Schilmiller et al., 2009; Wagner et al., 2009; Li et al., 2009; Song & Wang, 2011),

altered morphology (Elkind et al., 1990; Piquemal et al., 1998; Jones et al., 2001; Franke et al., 2002) and browning tissues (Bout & Vermerris, 2003; Xu et al., 2011; Saballos et al., 2012). Terms related to auxin efflux were identified too and it is known its importance in regulation of growth. Since the auxin hormone effects are concentration dependent and it is mostly produced in the meristematic and other specific regions (Blakeslee, Peer & Murphy, 2005; Zhao, 2018), the transport and distribution of auxin within plant tissues constitutes an essential aspect of its function in plant organogenesis and morphogenesis (Woodward & Bartel, 2005). This transport is achieved through influx and efflux carrier proteins, providing essential directional and positional information for developmental processes, such as vascular differentiation, apical dominance, organ development and tropic growth (Benkova et al., 2003; Blancaflor & Masson, 2003; Friml et al., 2003; Blilou et al., 2005; Grieneisen et al., 2007).

Furthermore, flavonol biosynthetic process, another enriched term found in our results, is reported to regulate plant growth and development by regulating auxin transport, with effects mainly in root elongation, quantity and gravitropic response (Jacobs & Rubery, 1988; Brown et al., 2001; Santelia et al., 2008; Grunewald et al., 2012). The flavonols may have influence on auxin transportation by different mechanisms, like by affecting the transcriptions of genes encoding auxin transport proteins (Peer et al., 2004), by being kinase inhibitors modulating the phosphorylation status of auxin transport proteins (Agullo et al., 1997; Peer & Murphy, 2007), or by altering the redox state of the cell (Fernández-Marcos et al., 2013). In addition to that, flavonols have antioxidant functions, acting in stress response to UV radiation, wounding, drought, metal toxicity and nutrient deprivation, conditions that result in the accumulation of reactive oxygen species (ROS), which can damage cellular components and consequently affect plant development (Winkel-Shirley, 2001; Baskar, Venkatesh & Ramalingam, 2018; Agati et al., 2020). The list of terms associated with plant growth, development and stress response continues with folic acid biosynthetic process (Stakhove et al., 2000; Gorelova et al., 2017), galactolipid metabolic process (Kobayashi et al., 2007; Jouhet et al., 2007; Botté et al., 2011) and cellular response to cold.

In this sense, considering its ability to identify regions with known genes associated with the traits, another important aspect of the methodology is to put light on not annotated genes that should be investigated. In our results, more than half of the identified genes linked to the major importance markers did not have functional annotation, and more than that, some of them seems to be very important, having multiple copies and being associated with various traits (Fig. 3). These genes/regions are important targets to expand the knowledge on the

agronomic traits metabolic regulation and represents valuable information that can be applied in the species breeding.

Additionally, for going further in our multi-omic investigation and understanding of the metabolic pathways and regulation that controls the evaluated agronomic traits. We constructed a co-expression network and isolated the previously identified genes and their co-expressed (Figure 4-A). This integration has been employed in some species and produced interesting results (Calabrese et al., 2017; Schaefer et al., 2018; Yan et al., 2020; Francisco et al., 2021), the main difference is that instead of using GWAS to identify marker-phenotype associations, we employed genomic prediction with feature selection, similar to the method applied in the study of mosaic virus resistance in sugarcane (Pimenta et al., 2022). In this aspect, the capability of networks to simulate complex biological systems and infer novel biological associations has been revolutionizing molecular biology research (D'haeseleer et al., 2000; Liu et al., 2020), enabling the study of regulatory relationships, metabolic pathway inferences and annotation transference (Rao & Dixon, 2019). Based on the “guilt-by-association” principle, which in the case of co-expression networks, states that genes with correlated biological functions tend to interact in the networks (Oliver, 2000, Wolfe et al., 2005, Childs et al., 2011). We could expand our set of identified genes to their co-expression modules and have a broader profile of the metabolic pathways acting in the phenotypes, and more than that, the annotated genes in the modules can be used to infer the biological functions of the not annotated genes.

Even though the investigation of the enriched terms in the agronomic traits network showed various terms with no clear relation to the phenotypes evaluated, such as seed maturation, meiosis processes or pollen sperm cell differentiation (Supplementary Table S11). The network expanded the genes related to the enriched terms already discussed, and enabled the identification of new genes involved in biological processes mainly related to DNA integrity, stability and metabolism, acting in mismatch repair, telomere capping and duplex unwinding, all reported to at some extend, affect the normal growth and development of plants (Karthika et al., 2020, Kim & Kim, 2018, Tuteja, 2003); related to the abscisic acid (ABA) transport, where the modulation of the hormone levels in tissues and cells is critical for balancing defense and growth processes when not in an optimal environments, with an important function controlling stomatal closure (Seo & Koshiba, 2011; Chen et al., 2020); related to the regulation of the circadian rhythm, which gives the plants the capacity to not only deal with the daily environmental changes but anticipate and prepare for them beforehand (Kim et al., 2017; Millar, 2016; Creux & Harmer, 2019), where the gene

ELF4-LIKE 4, a circadian rhythm key gene (Doyle et al., 2002), had its importance evidenced by being one of the genes with highest degree value in the network (Supplementary Table S12); and related to response to chitin, an important part of the plants immune system that is activated in the presence of pathogens such as fungi, arthropods and nematodes egg-shells (Kombrink et al., 2011; Sánchez-Vallet et al., 2015).

Furthermore, by isolating in the network the genes associated with each season, we could investigate metabolic processes affecting the plant development and production in the wet and dry periods. In our results, we identified in both seasons enriched terms for auxin efflux and flavonol biosynthetic process which as already discussed regulates auxin transport, indicating the importance of the hormone regardless of the season. For the wet season, beyond the abscisic acid transport already cited, we had terms reported to influence plant development such as isoleucine biosynthetic process (Yu et al., 2013) and response to nematodes, a pathogen capable of modifying plant physiology, development, metabolism and immunity (Eves-van den Akker, 2021). Even though being related to the phenotypes, we could not find in the literature studies specifically associating these processes with wet/rainy season. Differently, in the dry network we had response to water deprivation and protein transport terms enriched, which is evidence of the metabolic machinery necessary to deal with the abiotic stress.

Our work is innovative in different aspects and represents a great advance in the knowledge of molecular breeding techniques that can be applied in tropical forages. It is the first study investigating the applicability of GWFP in an *Urochloa* species and more than that, the first time that feature selection and machine learning algorithms are employed in GWFP to not only enhance the prediction metrics but drastically reduce the number of makers necessary for the prediction. Additionally, in a multi-omic approach, the markers selected were integrated with transcriptome data to model a co-expression network capable of offering insights into the regulation of plant growth and biomass production in the species. The results show that molecular breeding has a great potential to reduce breeding costs, accelerate the release of new varieties and provide means to metabolic investigations even in orphan species with high genomic complexity such as tropical forages.

Supplementary Information

1- Supplementary Materials and Methods

Supplementary Figure S1. Climatological water balances through available water capacity (AWC = 100mm) in a 10 days scale during the period of 2012 November to 2014 January in Embrapa Gado de Corte, Campo Grande, MS.

2 - Supplementary Results

Supplementary Figure S2. Box plots of the scaled phenotype clippings. DM, LDM, SDM, GM and RG stands for dry matter, leaf dry matter, stem dry matter, green matter and regrowth.

Supplementary Figure S3. Heat map showing the correlation between all trait clippings. Red lines separate different phenotypes. DM, LDM, SDM, GM and RG stands for dry matter, leaf dry matter, stem dry matter, green matter and regrowth.

Supplementary Figure S4. Principal component analysis scatter plot of the families phenotypes. The axes represent the first and second principal components, which explain 75.7% and 9.5% of the variance, respectively.

Supplementary Figure S5. Principal component analysis scatter plot of the families genotyping, total of 28,106 markers. The axes represent the first and second principal components, which explain 38.9% and 18.3% of the variance, respectively.

Supplementary Figure S6. Principal component analysis scatter plot of the families genotyping, considering only the Major Importance markers (69 markers). The axes represent the first and second principal components, which explain 58% and 9.5% of the variance, respectively.

Supplementary Figure S7. Venn's diagrams showing the logic relation between the sets of markers identified for each phenotype. (A) Total 283 markers from the FI-2 data set and (B) 69 markers selected by the Gini importance condition. DM, LDM, SDM, GM and RG stands for dry matter, leaf dry matter, stem dry matter, green matter and regrowth.

2.1 - Transcriptome assembly, evaluation and annotation

To obtain a set of genes expressed by the species and later evaluate their co-expression, we used a previously published transcriptome of 11 *U. ruziziensis* genotypes. The sequencing of the libraries produced a total of 1.7 billion reads, of which 95.5% (Supplementary Table S9) were retained and used in the *de novo* assembly. The transcriptome comprised 575,524 transcripts, of which 223,593 were unigenes with a transcript N50 length of 1,227 bp. After the expression level filtration, the set was reduced to 288,487 transcripts, representing 49,445 unigenes. The evaluation of the assembly completeness was done comparing the 49,445 unigenes to the Viridiplantae database. From the 425 total BUSCO groups searched, we found 297 Complete sequences (69.8%), 48.2% as a single-copy and 21.6% as duplicated copies, in addition to 74 (17.4%) and 54 (12.8%) fragmented and missing sequences, respectively.

In the functional annotation, we aligned the transcripts to the UniProt database and obtained 197,045 GO terms associated using the Trinotate software; from those, 6,156 were unique GO terms. This set of genes and GO terms were used for the biological process GO terms enrichment of the genes linked to the Major importance markers and the sets obtained in the co-expression networks.

Supplementary Figure S8. *Urochloa ruziziensis* 11 genotypes transcriptome gene co-expression network (GCN).

Supplementary Tables

Supplementary Table S1. Progeny means narrow sense heritability (h^2) for all phenotype clippings.

RESUMO DOS RESULTADOS

CAPÍTULO I

- (1) Desenvolvemos uma metodologia para identificação de contaminantes oriundos de apomixia, autofecundação ou cruzamento indesejado, em populações biparentais de espécies tetra/hexaploides. A metodologia foi capaz de identificar 100% dos contaminantes em populações simuladas com 200 indivíduos e genotipados com pelo menos 689 marcadores moleculares;
- (2) Aplicamos a metodologia para a identificação de contaminantes em três populações reais de forrageiras tropicais. Nas populações tetraplóides de *U. decumbens* e *M. maximus*, foram identificados 2 e 52 amostras como clones apomíticos. Já na população hexaploide de *U. humidicola*, foram identificadas 65 amostras como clones apomíticos;
- (3) Implementamos a metodologia em um R Shiny web app com visualização gráfica chamado PolyCID.

CAPÍTULO II

- (1) Comparamos modelos convencionais e de aprendizado de máquina para predição genômica em famílias de meios irmãos de características relacionadas a crescimento e produção de biomassa. O melhor modelo (RKHS) apresentou uma média aproximada de 0.76 de habilidade preditiva utilizando o conjunto completo de marcadores;
- (2) A seleção de features foi capaz de reduzir o conjunto de marcadores necessários para fazer as predições, e aumentou a habilidade preditiva dos modelos. O melhor modelo (RF) obteve uma média aproximada de 0.89 de habilidade preditiva utilizando conjuntos reduzidos de aproximadamente 11 marcadores;
- (3) Utilizando a métrica Importância Gini do modelo RF, selecionamos 69 marcadores de maior importância como associados as características agrônômicas preditas;
- (4) Identificamos 217 genes (obtidos no transcriptoma) fisicamente ligados aos 69 marcadores selecionados, e construímos um mapa físico relacionando os marcadores, genes, características fenotípicas e estações. Do total de genes identificados, 100 tiveram anotação funcional;
- (5) O enriquecimento dos termos GO dos genes identificados mostrou que eles estão relacionados principalmente aos processos biossintéticos de lignina, flavonol e ácido fólico, no transporte de auxina e no processo metabólico de galactolipídeos, vias metabólicas que atuam no crescimento e produção de biomassa;

- (6) Utilizando o transcriptoma, construímos uma rede global de co-expressão, e isolamos os genes previamente identificados junto aqueles co-expressos como primeiros e segundos vizinhos. A rede dos genes associados às características de interesse possui 2704 genes (nós) e 3453 arestas;
- (7) O enriquecimento dos termos GO dos genes presentes na rede de co-expressão isolada mostrou que, além das vias metabólicas já citadas, vários genes estão relacionados ao metabolismo e manutenção de DNA, resposta a estresses bióticos e regulação do ciclo circadiano;
- (8) Identificamos genes na rede com alto grau de conexões indicando sua atuação em conjunto com muitos outros genes, como proteínas ribossomais que influenciam na expressão de outros genes, proteína ELF4-LIKE 4 associada ao ciclo circadiano e proteína 14-3-3 zeta associada a crescimento, desenvolvimento e resposta a estresses;
- (9) Separando a rede em temporada de seca e chuva, identificamos termos enriquecidos compartilhados relacionados à biossíntese de flavonol, transporte de auxina e replicação de DNA durante a mitose. Foram identificados termos específicos para a temporada de chuva relacionados a transporte de ácido abscísico, biossíntese de isoleucina e resposta a nematóides, enquanto para temporada de seca, termos relacionados ao transporte de proteínas, biossíntese de fosfato piridoxal e a resposta a quitina e à privação de água.

CONCLUSÃO

Apesar do surgimento das tecnologias de sequenciamento de nova geração e a consequente redução drástica nos custos de sequenciamento de DNA e RNA que aconteceu no fim da década de 2000, programas de melhoramento de espécies órfãs que possuem genomas de alta complexidade, como as forrageiras tropicais, ainda passam por dificuldades para implementar o uso desses dados no melhoramento e desenvolver novas variedades com maior ganho genético. Nesse sentido, esta tese teve como objetivo investigar o uso desses dados em forrageiras tropicais, especialmente espécies do gênero *Urochloa*, para produzir métodos, ferramentas e conhecimentos que auxiliem suas aplicações nos programas de melhoramento.

Quanto à metodologia e a ferramenta (polyCID) desenvolvidas no **Capítulo I** para a identificação de contaminantes em populações biparentais tetra/hexaplóide, concluímos que marcadores do tipo SNP, desde que genotipados em dosagens alélicas e em quantidade suficiente, são eficientes para a identificação de contaminantes. Além disso, a ferramenta proporciona uma análise de fácil execução e entendimento que a depender do tamanho do conjunto de dados pode ser realizada em poucos minutos.

No **Capítulo II**, realizamos uma análise multi ômica com dados de *U. ruziziensis*, integrando métodos como predição genômica e redes de co-expressão. Concluímos que GWFP é um método aplicável a espécie, e que técnicas de aprendizado de máquina integradas com seleção de features são capazes de melhorar as métricas de predição e reduzir o número de marcadores necessários para a predição, evidenciando que a abordagem representa uma grande redução de custos para o programa de melhoramento. Além disso, os marcadores selecionados podem ser considerados como possíveis QTL e utilizados para a identificação de genes putativos com influência no fenótipo. Com a integração dos genes identificados e a rede de co-expressão modelada com dados de transcriptoma, é possível através dos módulos de co-expressão estender a investigação para vias metabólicas mais amplas e inferir funções para genes não anotados.

Em relação a tese como um todo, a principal conclusão do trabalho é que muitos dos métodos e ferramentas do melhoramento molecular, desenvolvidos e amplamente aplicados em plantas modelo, com as devidas adaptações podem ser utilizados no melhoramento de espécies órfãs com genomas de alta complexidade como as forrageiras tropicais. Os resultados apresentados nesta tese e em outros trabalhos fornecem um arcabouço de conhecimento capaz de ampliar significativamente o uso do melhoramento molecular nos programas de melhoramento dessas espécies.

PERSPECTIVAS

Com o desenvolvimento da ferramenta polyCID para a identificação de contaminantes, é esperado que inicialmente ela auxilie programas de melhoramento que estejam trabalhando na construção de mapas genéticos de ligação. A metodologia foi criada para lidar com dados do tipo SNP com informação de dosagem alélica, que são os dados necessários para a construção de mapas genéticos em poliploides. Com a contínua redução dos custos para a genotipagem, espera-se que no futuro os programas consigam fazer a análise de forma rotineira em seus cruzamentos, reduzindo as perdas no ganho genético devido a presença de contaminantes.

Em relação a investigação da aplicabilidade de GWFP em *U. ruzizensis* para as características agronômicas de crescimento e produção de biomassa, os resultados foram promissores e, conseqüentemente, a abordagem poderia ser testada em outras características, especialmente as de valor nutricional, as quais essa mesma população já foi fenotipada. A espécie é conhecida por ter alta qualidade nessas características, o que a torna ainda mais importante, servindo para cruzamentos interespecíficos com espécies mais produtivas. Espera-se que com resultados como esses, os programas se sintam mais confiantes em de fato implementar a metodologia em seus programas.

ANEXOS

Declaração de Bioética

COORDENADORIA DE PÓS-GRADUAÇÃO
INSTITUTO DE BIOLOGIA
Universidade Estadual de Campinas
Caixa Postal 6109, 13083-970, Campinas, SP, Brasil
Fone (19) 3521-6378, email: cpgeb@unicamp.br

DECLARAÇÃO

Em observância ao §5º do Artigo 1º da Informação CCPG-UNICAMP/001/15, referente a Bioética e Biossegurança, declaro que o conteúdo de minha Tese de Doutorado, intitulada "***Identificação de contaminantes e análises multiômicas aplicadas no melhoramento molecular de forrageiras tropicais poliplóides***", desenvolvida no Programa de Pós-Graduação em Genética e Biologia Molecular do Instituto de Biologia da Unicamp, não versa sobre pesquisa envolvendo seres humanos, animais ou temas afetos a Biossegurança.

Assinatura: 
Nome do(a) aluno(a): Felipe Bitencourt Martins

Assinatura: 
Nome do(a) orientador(a): Anete Pereira de Souza

Data: 7 de fevereiro de 2023

Declaração de Direitos Autorais

Declaração

As cópias de artigos de minha autoria ou de minha co-autoria, já publicados ou submetidos para publicação em revistas científicas ou anais de congressos sujeitos a arbitragem, que constam da minha Dissertação/Tese de Mestrado/Doutorado, intitulada **Identificação de contaminantes e análises multiômicas aplicadas no melhoramento molecular de forrageiras tropicais poliplóides**, não infringem os dispositivos da Lei n.º 9.610/98, nem o direito autoral de qualquer editora.
